Currently marketed benzodiazepines are similar to each other in that they all have the 1,4-benzodiazepine ring system. Modification of this ring system results in benzodiazepines with somewhat different properties (Figure 22-1).

Pharmacokinetics and Disposition

Knowledge of benzodiazepine pharmacokinetics helps the clinician choose the most appropriate benzodiazepine for the patient and also guides its correct use. Benzodiazepines differ in their pharmacokinetic properties, such as absorption, distribution, and elimination (Table 22-1). On the other hand, all benzodiazepines are similar in that to some degree they all possess anxiolytic, muscle relaxant, sedative-hypnotic, and anticonvulsant properties. The belief that one benzodiazepine is primarily anxiolytic while another is primarily hypnotic is not based on scientific evidence (Greenblatt *et al.* 1983a, 1983b). The preferential selection of a benzodiazepine for one market over another is usually dictated by its pharmacokinetic properties.

TABLE 22-1. Pharmacokinetics of benzodiazepines

Group	**Medication**	**Metabolism**	**Cytochrome P450 (CYP) enzyme(s)**	**Half-life ($t_{1/2}$), hours[a]**
Desmethyldiazepam	Diazepam	Oxidation	2C19, 3A4	26-50
	Bromazepam[XUS]	Oxidation	3A4, 2C19	1-5
	Clorazepate	Oxidation	3A4	40-50
	Prazepam[DISC]	Oxidation	2C19, 3A4	> 21
	Chlordiazepoxide	Oxidation	3A4	> 21 (24-48)
Desalkylflurazepam	Flurazepam	Oxidation	2C19, 3A4	40-120[b]
	Clonazepam	Oxidation	3A4	24-56 (17-60)
Triazolobenzodiazepine	Triazolam	Oxidation	3A4	2-4 (1.5-5.5)
	Alprazolam	Oxidation	3A4	10-15 (6-27)

Note. DISC = Product is FDA approved but all approved generic and brand name products have been discontinued (per the FDA Orange Book [U.S. Food and Drug Administration 2023]); NA = not applicable; XUS = Product not FDA approved at present (August 2023).

[a] Apparent half-life can be dosage form-dependent for sustained-and delayed-release products. Also, half-life may be longer in the setting of overdose, in the presence of other compounds that can inhibit elimination enzyme activity, in the context of impaired organ function, and in other circumstances/settings.

[b] For flurazepam, parent drug 2.3 hours; metabolite 74-113 hours.

Rate of Absorption

Benzodiazepines that are rapidly absorbed from the gastrointestinal tract enter and peak in the circulation quickly and have a quicker onset of action than those that are absorbed more slowly. Diazepam and clorazepate are rapidly absorbed and act quickly, chlordiazepoxide and lorazepam have intermediate rates of absorption and onset of action, and prazepam is slowly absorbed and has a slower onset of action.

Gastrointestinal absorption of benzodiazepines is dictated by intrinsic physiochemical properties of the drug and characteristics of the formulation, such as particle size (Greenblatt *et al.* 1983a, 1983b). Absorption of a benzodiazepine given intramuscularly is dictated by other factors. For example, chlordiazepoxide and lorazepam, when given orally, are absorbed at similar rates in the gastrointestinal tract. When given intramuscularly, lorazepam is more reliably, rapidly, and completely absorbed than chlordiazepoxide (Greenblatt *et al.* 1979, 1982b, 1983a, 1983b).

Lipophilicity

The lipid solubility (lipophilicity) of a benzodiazepine at physiological pH influences the rate at which it crosses the blood-brain barrier by passive diffusion from the circulation, and this, in turn, determines the rapidity of onset of action and intensity of effect (Greenblatt *et al.* 1983a, 1983b). Highly lipophilic drugs cross the blood-brain barrier rapidly, and although all benzodiazepines are highly lipophilic, they differ in their degree of lipophilicity. Because diazepam is more lipophilic than lorazepam or chlordiazepoxide, anxiety reduction and onset of side effects are more rapid.

Duration of Action

With benzodiazepines, the duration of therapeutic action is determined mainly by the rate and extent of drug distribution rather than by the rate of elimination. Benzodiazepine distribution is determined largely by its lipophilicity. Diazepam, which has a longer half-life than lorazepam, has a shorter duration of clinical action after a single dose. The reason is that diazepam, because of its greater lipid solubility, is more extensively distributed to peripheral sites, particularly to fat tissue. Consequently, it is more rapidly moved out of the blood and brain into inactive storage sites, and its CNS effects end more rapidly. Conversely, less lipophilic benzodiazepines maintain their effective brain concentrations longer because they are less extensively distributed to the periphery (Greenblatt *et al.* 1983a, 1983b).

Rate of Elimination

The rate of elimination (i.e., elimination half-life) influences the speed and extent of accumulation and the time to reach a steady state. It also influences the time for drug washout after termination of multiple doses. Accumulation is slow and extensive when the half-life is long. When the rate of metabolic removal equals the rate of ingestion, the drug is said to have reached a steady state. A useful rule is that when treatment has been in progress for at least four times as long as the elimination half-life, the accumulation process is more than 90% complete (Greenblatt *et al.* 1983a, 1983b). When drugs with long elimination half-lives are stopped, they are washed out slowly, and the symptoms recur gradually over a period of days, with less intense or sudden rebound phenomena (Greenblatt *et al.* 1981, 1982a; Kales *et al.* 1982). Side effects from long-term treatment with long-half-life benzodiazepines last longer than with short-half-life benzodiazepines. Because of greater drug accumulation with long-half-life benzodiazepines, frequent drowsiness and sedation are a theoretical concern (Greenblatt *et al.* 1981). Tolerance to sedation occurs with long-term use, even though the plasma drug level remains the same. However, as a matter of caution it is prudent to choose a benzodiazepine with a shorter or intermediate half-life for older adults (Greenblatt *et al.* 1982c), people operating heavy machinery, and those engaging in high-level intellectual tasks.

Biotransformation Pathway

Benzodiazepines are metabolized in the liver by microsomal oxidation or by glucuronide conjugation. Hepatic disease, age, several medical illnesses, and several drugs that impair oxidizing capacity, such as cimetidine, estrogens, and the hydrazine monoamine oxidase inhibitors, all influence the oxidation pathway. These factors

usually magnify the side effects of the benzodiazepine. Consequently, for older adults and patients with liver disease, benzodiazepines that are conjugated (e.g., lorazepam, oxazepam, and temazepam--the LOT trio) are safer than benzodiazepines that are metabolized by oxidation (e.g., diazepam and alprazolam).

Dosing: Sustained-Release Formulations

Dosing schedules of benzodiazepines should be dictated by knowledge about the rate of distribution rather than by information about elimination half-life. Sustained-release formulations of several benzodiazepines have been introduced to provide 24 hours of anxiolysis. In our experience, the sustained-release forms of alprazolam, clorazepate, diazepam, and adinazolam, and the recently approved lorazepam extended-release (XR) formulation, have a duration of therapeutic action of approximately 12 hours, not 24 hours as their indicated use suggests. Standard alprazolam has a duration of action of 4-6 hours, clonazepam has a duration of action of 7 hours, and other standard-formulation benzodiazepines are within this 4-to 7-hour range.

Mechanism of Action

Benzodiazepines produce anxiolysis by their effect on the GABA-benzodiazepine receptor complex. GABA is synthesized from glutamic acid, which is also the most abundant free amino acid in the CNS. Like serotonin, norepinephrine, and dopamine neurons, the presynaptic GABA neuron has a reuptake pump that transports GABA from the synapse for storage or destruction by GABA transaminase. GABA has three target receptors: $GABA_A$, $GABA_B$, and $GABA_C$. The chloride ion channel is controlled by $GABA_A$.

Four distinct pharmacological properties have been described for the benzodiazepine receptor: anxiolytic, hypnotic, anticonvulsant, and muscle relaxation effects. $GABA_A$ receptors with a_2 (or a_3) subunits mediate the anxiolytic effects, whereas $GABA_A$ receptors with an a_1 subunit mediate the sedative-hypnotic actions. Most benzodiazepines interact with both these receptor subtypes. Typically, when GABA occupies the $GABA_A$ receptor site, opening and closing of the chloride channel occur more frequently, and this effect is inhibitory. If at the same time a benzodiazepine binds to the nearby benzodiazepine receptor, the $GABA_A$ receptor is allosterically modulated, and GABA exerts a greater effect (greater frequency of opening and closing) on the chloride channel and conductance. Although GABA works alone at the GABA receptor, the action of GABA is stronger in the presence of a benzodiazepine. The benzodiazepine in the absence of GABA cannot influence the chloride channel by itself.

Therapeutic Uses

Because of their multiple pharmacological actions, benzodiazepines are useful in many areas of medical practice, such as induction of anesthesia, use as a muscle relaxant, and control of seizures. It is beyond the scope of this chapter to elaborate on these nonpsychiatric uses. In psychiatry, benzodiazepines are used to control anxiety, treat insomnia, and acutely manage agitation and withdrawal syndromes.

In the treatment of anxiety disorders, benzodiazepines have a greater effect in some disorders than in others. In panic disorder, they have a significant effect on all dimensions of the illness, with the exception of the core symptoms of depression. Alprazolam, for example, has been shown to be effective in panic disorder at a mean dosage of 5.7 mg/day (range 1-10 mg/day) (Ballenger *et al.* 1988; Chouinard *et al.* 1982; Cross National Collaborative Panic Study, Second Phase Investigators 1992; Sheehan *et al.* 1982, 1984, 1993). Rapid improvement was seen within the first week in the form of decreased panic attacks, phobic fears and avoidance, anticipatory anxiety, and disability. These benefits were shown to persist during a follow-up period of 8 months (Schweizer *et al.* 1993). Efficacy also has been established for lorazepam (Rickels and Schweizer 1986) and clonazepam (Pollack *et al.* 1993; Tesar *et al.* 1991). In the latter studies, clonazepam 2.5 mg/day was as effective and well tolerated as alprazolam 5.3 mg/day.

Despite the well-documented efficacy of benzodiazepines in panic disorder, they have been displaced in clinical practice by the SSRIs and SNRIs. However, some clinicians initiate treatment with both classes of drug simultaneously and then withdraw the benzodiazepine after 6 weeks. The benefits and practicality of this approach to treating panic disorder are reinforced by the findings from two studies (Goddard *et al.* 2001, 2008). The American Psychiatric Association Work Group on Panic Disorder (1998) guidelines for the treatment of panic disorder recommending SSRI monotherapy as the treatment of first choice have failed to achieve traction, as shown by the finding that more than two-thirds of the SSRI prescriptions in 2008 were accompanied by a concomitant benzodiazepine (Keller and Craske 2008). The study by Goddard *et al.* (2008) lends justification to the rationale for using the combination treatment more frequently and for considering it a reasonable alternative first-line treatment for many patients with panic disorder.

Three double-blind studies have shown the efficacy of benzodiazepines in the treatment of social phobia (i.e., DSM-5-TR [American Psychiatric Association 2022] social anxiety disorder) (Davidson *et al.* 1993; Gelernter *et al.* 1991; Versiani *et al.* 1997).

In a double-blind, placebo-controlled study, Rickels *et al.* (1993) found that the tricyclic antidepressant imipramine was better than diazepam in the treatment of generalized anxiety disorder without depression over 8 weeks. Imipramine showed a trend of being significantly better on the primary outcome measure (the Hamilton Anxiety Scale [Ham-A]) and was statistically superior to diazepam on the Psychic Anxiety factor of the Ham-A. Psychic anxiety includes the items of worry, anxious mood, tension, fears, and concentration problems. Diazepam and imipramine had identical endpoint Ham-A Somatic Anxiety factor scores, suggesting that they are equally effective against the somatic anxiety symptoms in generalized anxiety disorder. This suggests that imipramine is a better "anti-worry" medication than the benzodiazepine. Patients taking diazepam had an earlier response than those taking imipramine.

Generally, benzodiazepines are thought to be ineffective in the treatment of OCD.

Benzodiazepines are often prescribed for patients with PTSD. Although benzodiazepines may improve sleep and reduce agitation initially in PTSD, the weight of evidence suggests that in the longer term they are not particularly effective for the core symptoms of this disorder, and more-effective alternatives are preferable (Berger *et al.* 2009; Cifu *et al.* 2013; Guina *et al.* 2015; Jeffreys *et al.* 2012; Spaulding 2012). An added complication is that patients with PTSD have higher rates of DSM-IV (American Psychiatric Association 1994) substance abuse and dependence than the general population, which can further complicate their treatment. For all these reasons, benzodiazepine use in PTSD is discouraged by most clinical practice guidelines (e.g., American Psychiatric Association, British Association for Psychopharmacology, International Consensus Group on Depression and Anxiety, International Society for Traumatic Stress Studies, Veterans Affairs/Department of Defense) (American Psychiatric Association 2004; Baldwin *et al.* 2005; Ballenger *et al.* 2000; Foa *et al.* 2009; U.S. Department of Veterans Affairs and U.S. Department of Defense 2017). The strongest evidence for effective pharmacotherapy in PTSD is for SSRIs. A meta-analysis of medications used to treat PTSD found effect sizes of 0.49 and 1.38 for benzodiazepines and SSRIs, respectively (Van Etten and Taylor 1998).

Studies have compared intramuscular clonazepam against intramuscular haloperidol in the management of acute psychotic agitation. Clonazepam reduced agitation, but haloperidol had a more rapid onset (Chouinard *et al.* 1993). Patients with schizophrenia have high levels of anxiety and frequently experience panic attacks. Overall, it appears that benzodiazepines have a role in the acute management of agitation, and their use can reduce the need for antipsychotics or the dosage of antipsychotics used.

Side Effects and Toxicology

Benzodiazepines are among the safest drugs, but unwanted effects do occur. The first 1,4-benzodiazepines, such as diazepam and flurazepam, had slow rates of elimination and low receptor-binding affinities. Their main side effect was excessive daytime sleepiness. The late 1970s saw the introduction of the 1,4-benzodiazepines flunitrazepam and lorazepam, which had shorter half-lives and were more potent. These drugs were associated with greater efficacy but also with more rapid development of tolerance and significant withdrawal problems. The triazolobenzodiazepines were introduced in the 1980s and were even more potent and had even shorter half-lives. They also have been found to be associated with amnesia, daytime anxiety, early morning insomnia, and withdrawal problems such as rebound insomnia, anxiety, and seizures (Noyes *et al.* 1986). Short-term benzodiazepine use can decrease sleep time, increase rapid eye movement (REM) sleep, decrease slow-wave sleep, increase stage 2 non-REM sleep, and decrease delta wave sleep (Poyares *et al.* 2004; Morin *et al.* 2005). However, many benzodiazepines are approved for and are effective for the treatment of insomnia (Bostwick *et al.* 2012).

Sedation and drowsiness are common, occurring in 4%-9% of patients taking benzodiazepines. Ataxia occurs in up to 2%. The drowsiness tends to disappear with time or a reduction in dosage (Greenblatt *et al.* 1982b; Miller 1973; Svenson and Hamilton 1966). Benzodiazepines may impair psychomotor performance. Shortly after administration at their peak concentration, most benzodiazepines cause anterograde amnesia (Lister *et al.* 1988). These effects depend on potency and route of administration (Bixler *et al.* 1979). Overall, this memory impairment appears to be independent of the degree of sedation produced by the drug (Scharf *et al.* 1988). Benzodiazepine-treated

subjects are often unaware of or underestimate the extent of their memory impairment (Roache and Griffiths 1985, 1987).

Hyperexcitability phenomena such as early morning awakening and rebound anxiety and nervousness are more likely with the short-half-life, high-potency benzodiazepines such as triazolam, alprazolam, lorazepam, and brotizolam (Kales *et al.* 1983, 1986, 1987; Vela-Bueno *et al.* 1983). Treatment-emergent hostility (Rosenbaum *et al.* 1984) may be seen in up to 10% of patients receiving benzodiazepines. Patients may become paradoxically aggressive, destructive, and sexually inappropriate in ways that are out of character on benzodiazepines, especially when combined with alcohol or when taken in dosages that are too high acutely. These complications are usually transient but can cause legal problems for the patient (Lader 1990; Jones *et al.* 2011).

These side effects are most likely to appear early in treatment, are unrelated to pretreatment impulsivity, and have been reported with all benzodiazepines except for oxazepam. Treatment-emergent mania has been reported with alprazolam (Goodman and Charney 1987; Pecknold and Fleury 1986; Strahan *et al.* 1985).

Since the 1960s, benzodiazepines have been found to produce anterograde amnesia, even with oral dosing (Lister 1985). The deficit is one of disrupted consolidation and not impairment of memory retrieval. The degree of amnesia can range from minimal inability to retain isolated pieces of information to total inability to recall any activities that occurred during a specific period. Whether some benzodiazepines are more likely than others to produce amnesia remains an unresolved question.

Cognitive Impairment and Risk of Alzheimer's Disease

Some publications have raised concerns that the long-term use of benzodiazepines may lead to cognitive and other impairments that persist long after the drugs have been discontinued. Abnormal CT scans were reported for long-term users of benzodiazepines in one study (Lader *et al.* 1984) but not in others (Poser *et al.* 1983; Rickels 1985). Busto *et al.* (2000) found no difference in the CT brain scans of patients taking benzodiazepines compared with control subjects. Long-term benzodiazepine users have been compared with control subjects and found to have cognitive impairments that reversed on reexamination after taper (Golombok *et al.* 1988; Lucki *et al.* 1986; Rickels *et al.* 1999; Sakol and Power 1988). Another study found that after long-term use, if the benzodiazepine was stopped, there was only partial recovery even after 6 months (Tata *et al.* 1994).

Billioti de Gage *et al.* (2014) reported inferential evidence suggesting that the use of benzodiazepines for longer than 3 months may be associated with an increased risk of Alzheimer's disease. They used a case-control design to minimize sampling bias and sampled subjects 6 years before the official diagnosis of Alzheimer's disease to control for "reverse bias" (the possibility that Alzheimer's disease resulted in benzodiazepines being used before the onset of the dementia). Salzman and Shader (2015) wrote a rejoinder to this study highlighting its methodological limitations and offering alternative interpretations for the findings. They pointed out that the results "could be interpreted to suggest that benzodiazepine use does not cause increased Alzheimer's disease, but Alzheimer's disease causes an increased need for benzodiazepine treatment in some patients" (p. 2), notably for the prodromal anxiety and insomnia so frequently associated with this illness. In their editorial, Balon *et al.* (2015) urged caution in the interpretation of the results and noted that it was "premature to conclude that benzodiazepines are a causative factor in a multidimensional disorder such as Alzheimer's disease" (Balon *et al.* 2015, p. 244).

Pariente *et al.* (2016) reviewed the literature on the association between benzodiazepine use and the risk of dementia disorders. Nine of the 11 studies reported a harmful effect; 1 study reported a protective effect; and the most recent, largest, best controlled, and most prospectively designed study found no effect. The problem in interpreting a finding of any such association in an inadequately controlled meta-analytic study is that both anxiety and sleep disturbances are common prodromal symptoms in dementia. A lack of adequate controls confounds the interpretation of results in these studies.

A *BMJ* study (Gray *et al.* 2016) followed 3,434 adults ages 65 years and older for 7 years. None had dementia at study initiation; 23% developed dementia by the end of the study. Gray and colleagues used computerized pharmacy data to assess benzodiazepine use. They found no link between the highest level of benzodiazepine use (on average, 1 year of daily use) and dementia or cognitive decline. A small increased risk for dementia was seen in people with moderate (1-4 months) and low (up to 1 month) levels of benzodiazepine use, but not in those using benzodiazepines for longer than 4 months. The authors concluded that the pattern of findings "does not support the theory that cumulative benzodiazepine use at the levels observed in our population is causally related to an increased risk for dementia or cognitive decline" (Gray *et al.* 2016, p. 8). A recent 2020 study of 235,465 Danish adults with affective disorder found no association between benzodiazepine use and later development of dementia. The same study found that lower benzodiazepine use was associated with risk of dementia, but higher benzodiazepine use was not (Osler and Jorgensen 2020).

Practice guidelines recommend that benzodiazepines be avoided in Alzheimer's disease and restricted to short-term, as-needed use by older adults (Madhusoodanan and Bogunovic 2004; Salzman 1990). However, others may agree with the comment by Salzman and Shader (2015), both seasoned and knowledgeable psychopharmacologists, that "experienced geriatric clinicians often find that judicious use of low-dose, short half-life benzodiazepines reduces stress, promotes daytime functioning, and assists in sleep onset; elderly patients themselves report that they would gladly forgo short-term memory reduction in exchange for a calmer daytime and reliable sleep onset" (p. 2).

Drug-Drug Interactions

Antacids may slow the rate of benzodiazepine absorption, but not the extent of absorption (Greenblatt *et al.* 1983a, 1983b). For example, diazepam peak concentrations are 30% lower when antacids are administered concurrently; however, there is no effect on the extent of absorption (e.g., AUC), and the time of peak concentration is delayed by an average of 20-25 minutes (Genentech 2016). An acid medium is needed for conversion of clorazepate to desmethyldiazepam, the active metabolite, which is then absorbed (Shader *et al.* 1978).

In the liver, benzodiazepines are metabolized by oxidation, reduction, or conjugation. Alprazolam, diazepam, clorazepate, prazepam, chlordiazepoxide, bromazepam, and halazepam are metabolized by oxidation; nitrazepam by reduction; and lorazepam, oxazepam, and temazepam by conjugation. Inhibitors of the oxidase system increase the half-life of benzodiazepines that are metabolized by this system. This accentuates the side effects, notably the sedation, ataxia, slurred speech, and imbalance. A decrease in dosage may solve this problem, or a switch to a benzodiazepine that is metabolized by conjugation may be needed.

Monoamine oxidase inhibitors and cimetidine may inhibit oxidative elimination of benzodiazepines (Greenblatt *et al.* 1984).

Oral contraceptives can also inhibit the oxidative system and thereby reduce the clearance and prolong the half-life of benzodiazepines, especially triazolam and alprazolam. Conversely, coadministration of intravenous lorazepam with contraceptive steroids (norethindrone acetate, 1 mg, and ethinyl estradiol, 50 mcg, for at least 6 months) to healthy females ($n = 7$) was associated with a 55% decrease in half-life and a 50% increase in the volume of distribution, resulting in an almost 3.7-fold increase in total clearance of lorazepam in comparison with healthy control females ($n = 8$). In this case, an increase in the lorazepam dosage may be required for patients who are concomitantly taking oral contraceptives (Hospira 2023).

Finally, coadministration of lorazepam (2 mg intravenously) with probenecid (500 mg orally every 6 hours) to 9 healthy volunteers increased lorazepam's half-life by 130% and reduced its total clearance by 45%. No change in volume of distribution was noted during probenecid cotreatment (Hospira 2023). The lorazepam dosage needs to be reduced by 50% when coadministered with probenecid.

A decline in oxidative elimination and clearance occurs with age or liver disease. In older adults, there is a 50% decrease in clearance, with a fourfold to ninefold increase in half-life and a twofold to fourfold increase in the volume of distribution (Peppers 1996). Heparinized patients should have partial thromboplastin time monitored more closely, because it is prolonged by benzodiazepines (Routledge *et al.* 1980). Because antidepressants such as fluoxetine, paroxetine, and nefazodone and protease inhibitors such as indinavir sulfate inhibit the cytochrome P450 enzyme 3A4, they inhibit the metabolism of triazolobenzodiazepines such as midazolam, alprazolam, and triazolam.

The FDA updated and revised the boxed warning on all benzodiazepines in September 2020. This change was driven by concerns over the coadministration of opioids and benzodiazepines. It advised caution when coprescribing benzodiazepines and opioids (U.S. Food and Drug Administration 2020). Nearly 2 million U.S. adults were coprescribed benzodiazepines and opioids between September 2016 and December 2017 (Zhang *et al.* 2019). The U.S. national rate for concomitant use of benzodiazepines and opioids rose from 9.8 to 62.5 per 10,000 outpatient visits between 1993 and 2016 (Hirschtritt *et al.* 2017). For patients taking benzodiazepines, the risk of death from drug overdose increases when they concomitantly take opioids and other CNS depressants. Benzodiazepine-related deaths increased approximately tenfold between 1999 and 2017 (from 0.5 per 100,000 in 1999 to almost 5 per 100,000 in 2017) (VanHouten *et al.* 2019). The FDA boxed warning also reaffirmed the need to warn patients about the risks of benzodiazepines; to assess the risk of abuse, misuse, and addiction for each patient; to prescribe the lowest effective dose for the shortest treatment duration; to taper patients off benzodiazepines slowly; and to conduct frequent follow-up with patients prescribed benzodiazepines (Hirschtritt *et al.* 2021; U.S. Food and Drug Administration 2020).

Clinical Issues

Despite decades of research, the optimal extent and duration of appropriate benzodiazepine use in the treatment of anxiety and related disorders remain unresolved. This is primarily because of concerns expressed by prescribers, regulators, and the public about issues such as tolerance, dependence, and abuse liability of this class of medications.

Tolerance

In a study of persistent users of alprazolam and lorazepam, Romach *et al.* (1995) found that most were not abusing these benzodiazepines, nor were they addicted to them; rather, they were using them appropriately for a chronic disorder and at a constant or a decreasing dosage. Soumerai *et al.* (2003) found no relationship between long-term use of benzodiazepines and escalation to high dosages in 2,440 long-term (at least 2 years) users of benzodiazepines and noted that escalation to a high dosage was very rare.

The cross-tolerance between the benzodiazepines, although good, is not perfect, and it is preferable to switch patients gradually from one benzodiazepine to another and to use comparable doses of each during the switch. One milligram of alprazolam is approximately equivalent to 0.7 mg of clonazepam, 10 mg of diazepam, or 1 mg of lorazepam.

Withdrawal

A withdrawal syndrome is defined as a predictable constellation of signs and symptoms involving altered CNS activity (e.g., tremor, convulsions, or delirium) after the abrupt discontinuation of, or a rapid decrease in, dosing of the drug (Rinaldi *et al.* 1988). Typically, a withdrawal syndrome from short-half-life benzodiazepines will intensify by the second day, will usually have peaked by day 5, and will begin to decrease and taper off by day 10. After 2 weeks, withdrawal symptoms usually have become minimal or are absent. Drug factors associated with withdrawal symptoms include length of use, dosage, potency, and rate of discontinuation. The most common symptoms are anxiety, restlessness, irritability, insomnia, agitation, muscle tension, weakness, aches and pains, blurred vision, and racing heart, in that order (O'Brien 2005). Nausea, sweating, runny nose, hypersensitivity to stimuli, and tremor are less common. Severe withdrawal symptoms, such as psychosis, seizures, hallucinations, paranoid delusions, and persistent tinnitus, are rare and are more likely to occur in abrupt withdrawal from high dosages of high-potency benzodiazepines and in older adults (American Psychiatric Association 1990; Lader 1990; Petursson and Lader 1981).

The minimum duration of use after which clinically significant withdrawal symptoms can be expected has not been definitively determined. At the end of any course of treatment with therapeutic dosages and a duration greater than 3 weeks, withdrawal of the benzodiazepine should be done as a very slow taper. This reduces the risk of unpleasant withdrawal symptoms and the danger of withdrawal seizures and minimizes rebound reactivation of the underlying anxiety disorder (Fontaine *et al.* 1984; Pecknold *et al.* 1988; Power *et al.* 1985).

A follow-up study of 123 benzodiazepine-dependent patients screened for entry into a tapered discontinuation program identified three groups: those who had completed the program (*n* = 48), those who had not (*n* = 38), and those who had undergone no drug tapering (*n* = 37). Among the completers, 73% remained benzodiazepine free at the end of 3 years, compared with 39% of the program noncompleters and 14% of the no-taper group (Rickels *et al.* 1991).

Addiction Potential

In our zeal to heal an anxiety disorder, are we creating a population of addicted patients? Much misinformation and concern are generated because terms such as *addiction* are often used pejoratively and without precise definition. For example, the terms *addiction, physical dependency,* and *withdrawal syndrome* are often used interchangeably. Some presume that a medicine's being associated with a withdrawal syndrome is evidence that the medicine is addictive. Some clinicians believe that benzodiazepines that require frequent dosing during the day are more addictive than those that require less-frequent dosing. In reality, frequency of dosing is a function of the duration of therapeutic action of the drug rather than of any innate addiction potential of the drug.

Most of the literature discussing benzodiazepine dependence liability uses older terminology. *Substance dependence* is defined as a maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by the presence of three (or more) of seven criteria, occurring at any time in the same 12-month period (American Psychiatric Association 2000). *Addiction,* by contrast, is defined as a chronic disorder associated with compulsive use of a drug, resulting in physical, psychological, or social harm to the user and continued use despite that harm (Rinaldi *et al.* 1988). Addiction involves both intense drug-seeking behavior and difficulty in stopping the drug use. If these criteria are used, benzodiazepines are not addictive drugs. *Physical dependence* is different from addiction and is defined as a physiological state of adaptation to a drug, with the development of tolerance to the drug's effects and the emergence of a withdrawal syndrome during prolonged abstinence. During withdrawal after chronic use, biochemical, physiological, or behavioral problems may be triggered. When used on a regular schedule, benzodiazepines are associated with physical dependence and have a withdrawal syndrome.

In DSM-5 (American Psychiatric Association 2013), the terms *abuse* and *dependence* are no longer used in relation to substances. Instead, DSM-5 uses the more neutral term *substance use disorder* to capture the wider range of disorders previously subsumed under *substance dependence* and *substance abuse.* DSM-5 also uses the terms *substance intoxication* and *substance withdrawal. Substance use disorder* is defined as a problematic pattern of substance use leading to clinically significant impairment or distress, as manifested by the presence of 2 (or more) of either 10 or 11 criteria, occurring within a 12-month period. At this time, no large epidemiological studies have used these new criteria in relation to benzodiazepines.

DSM-IV Substance Abuse

Studies of DSM-IV substance abuse use four criteria for benzodiazepine abuse. A benzodiazepine is being abused if it is used 1) to get high, 2) to promote psychological regression, 3) at dosages higher than prescribed, and 4) after the medical indication has passed (Dietch 1983). Based on this definition, the data suggest that the incidence of benzodiazepine abuse in clinical practice is low.

The incidence of benzodiazepine dependence in the therapeutic setting (among those for whom the drug is medically correctly prescribed) was estimated to be 1 case in 50 million patient-months (Marks 1978). Of these cases, 92% were associated with alcohol or other drugs of abuse. This estimate is probably on the low side because it is based on the number of published cases of dependence from 1961 to 1977.

In Basel, Switzerland, with a catchment area of 300,000 people, physicians were surveyed on the prevalence of benzodiazepine abuse in their patients. Only 31 patients were identified, for a prevalence of 0.01%, or 1 in 10,000. An additional 88 polysubstance abusers were identified (Ladewig and Grossenbacher 1988). In a random sample of all psychiatric hospitalizations over 15 years (1967-1983) in Sweden (*N* = 32,679), Allgulander (1989) found only 38 admissions for substance dependence on sedative-hypnotics. Twenty-one of the 38 patients had polysubstance abuse, and 17 had sedative-hypnotic abuse.

In another study of all medical and psychiatric hospitalizations (*N* = 1.6 million) in Stockholm County, Sweden, Allgulander (1996) found that 0.04% of "prescribed medication" users (including those using benzodiazepines) were ever admitted for medical problems relating to their drug use. In a study of 5,426 U.S. physicians randomly selected from the American Medical Association Physician Masterfile database, Hughes *et al.* (1992) found that although 11.9% had used benzodiazepines in the past year, only 0.6% met DSM-III-R (American Psychiatric Association 1987) criteria for benzodiazepine abuse, and only 0.5% met criteria for benzodiazepine dependence. In 1990, the American Psychiatric Association task force concluded that benzodiazepines were not normally drugs of abuse but noted that people who abused alcohol, cocaine, and opiates were at increased risk for benzodiazepine abuse (Salzman 1991).

A number of studies have noted no increase in dosage with long-term therapy lasting from 1 to 2.5 years, even though many of the patients had residual symptoms that would have benefited from a dosage increase or more intensive or additional treatment strategies (Pollack *et al.* 1986; Sheehan 1987). Nonanxious individuals and those with low anxiety levels reported finding benzodiazepines dysphoric (Reed *et al.* 1965), preferred placebo to diazepam

(Johanson and Uhlenhuth 1978, 1980), or rated their mood as less happy and pleasant after they were given 10 mg of diazepam (Svensson *et al.* 1980).

Although the data suggest that the prevalence of benzodiazepine abuse or dependence is generally low, this is not true among those who abuse alcohol and other drugs. In a study of chronic alcoholic patients who were high consumers of benzodiazepines, 17% got their benzodiazepines from nonmedical sources (Busto *et al.* 1983). In a study of 1,000 admissions to an alcohol treatment unit, 35% of the patients used benzodiazepines, but only 10% of the total sample were considered abusers or misusers (Ashley *et al.* 1978). A study of 427 patients seeking treatment in Toronto, Ontario, who met DSM-III (American Psychiatric Association 1980) criteria for alcohol abuse or dependence found that 40% were recent benzodiazepine users, and 20% had a lifetime history of benzodiazepine abuse or dependence. By contrast, only 5% of 108 alcoholic patients treated for a year with benzodiazepines for anxiety and tension showed evidence of abuse, and 94% believed that the medication helped them function and remain out of the hospital (Rothstein *et al.* 1976).

Benzodiazepines were the primary drug of abuse for one-third of polydrug abusers (Busto *et al.* 1986), 29% of 113 drug abusers admitting to the street purchase of diazepam in the previous month (Woody *et al.* 1975b), and 40% of patients at a methadone maintenance clinic (Woody *et al.* 1975a). The principal reasons for benzodiazepine use among drug-addicted patients are self-treatment of withdrawal symptoms, relief from rebound dysphoria, or potentiation of alcohol or street drug effects (Perera *et al.* 1987). In one study at an addiction treatment center, 100% of urine samples tested were positive for benzodiazepines, and 44% were positive for multiple nonprescribed benzodiazepines (Iguchi *et al.* 1993). A survey of patients at three different methadone maintenance clinics found that 78%-94% admitted to a lifetime use of benzodiazepines, and 44%-66% admitted to use in the prior 6 months. Snorting of benzodiazepines by people addicted to cocaine has been reported (Sheehan *et al.* 1991), primarily as a means of blunting the anxiogenic effect of cocaine and allowing for a more pleasant and "less edgy" high from that drug. Overall, the existing evidence suggests that benzodiazepine abuse is uncommon, except among people who abuse alcohol or other drugs. There was no significant increase in benzodiazepine dosage in a 2-year follow-up of either 113 "incident" or 992 "prevalent" users of benzodiazepines who had used benzodiazepines for at least 6 months (Willems *et al.* 2013).

Benzodiazepine misuse among adolescents is a growing concern. In a 2018 study of approximately 29,600 U.S. high school students (10th to 12th grade), 3.9% reported use of benzodiazepines (Johnston *et al.* 2019).

Despite extensive data and discussion on this topic, the issue remains and will continue to be controversial, with strong opinions held by opposing camps. Klerman characterized these camps as "pharmacological Calvinism" and "psychotropic hedonism" (Klerman 1972; Rosenbaum 2005). The middle ground suggests that we should not hesitate to prescribe benzodiazepines when it is reasonable, but we should exercise restraint in using them when we see any evidence of substance misuse or abuse (Pomeranz 2007).

Medicolegal Issues

In addition to the issues of dependence and withdrawal described in the previous section, use of benzodiazepines is associated with several potential medicolegal pitfalls. These include issues of teratogenicity, injury, and interaction with substances.

Benzodiazepine Use in Pregnancy and Lactation

Because anxiety disorders have their highest incidence in women during their childbearing years, the clinician may have to advise patients who are planning a pregnancy or who become pregnant while taking a benzodiazepine.

First and Second Trimesters

An important concern in the first and second trimesters is the possibility of teratogenic effects. Diazepam and desmethyldiazepam cross the placental barrier easily, and concentrations are higher in fetal blood than in maternal blood (Idanpaan-Heikkila *et al.* 1971). Early concern over benzodiazepine exposure in pregnancy arose because benzodiazepines

act on GABA receptors, and GABA is involved in palate shelf reorientation (Wee and Zimmerman 1983; Zimmerman and Wee 1984). The teratogenic effects of benzodiazepines are a matter of controversy, however. Exposure to benzodiazepines has been associated with teratogenic effects, including facial clefts and skeletal anomalies in newborns in some animal studies (Miller and Becker 1975; Walker and Patterson 1974; Wee and Zimmerman 1983; Zimmerman 1984; Zimmerman and Wee 1984) but not in others (Beall 1972; Chesley *et al.* 1991). Early studies in humans, including retrospective and case-control studies, reported an increased risk of oral clefts associated with diazepam (Aarskog 1975; Livezey *et al.* 1986; Safra and Oakley 1975; Saxen 1975; Saxen and Lahti 1974). However, these results have been criticized on methodological grounds and are contradicted by more recent prospective studies, case-control studies, and meta-analyses that show no increased risk of oral clefts related to benzodiazepine use in pregnancy (Altshuler *et al.* 1996; Bracken 1986; Czeizel 1987-1988; Dolovich *et al.* 1998; Ornoy *et al.* 1998; Pastuszak *et al.* 1996; Rosenberg *et al.* 1983; Shiono and Mills 1984).

Pooled data from seven cohort studies do not support an association between fetal exposure to benzodiazepines and major malformations (Dolovich *et al.* 1998).

Third Trimester and Labor

Two concerns associated with benzodiazepine use in the last trimester and through delivery are the possibilities of CNS depression and a withdrawal syndrome in the neonate. Signs of CNS depression may include hypotonia, lethargy, sucking difficulties, decreased fetal movements, loss of cardiac beat-to-beat variability, respiratory depression, and thermogenesis. These symptoms in the neonate are more likely with higher dosages and longer duration of benzodiazepine use by the mother. There have been numerous reports of "floppy infant syndrome" in babies born to women taking diazepam long term during pregnancy (Gillberg 1977; Haram 1977; Rowlatt 1978; Speight 1977). Neonatal withdrawal symptoms may include hyperactivity and irritability. The occurrence of neonatal withdrawal symptoms is well documented (Barry and St Clair 1987; Briggs *et al.* 1998; Cree *et al.* 1973; Fisher *et al.* 1985; Gillberg 1977; Haram 1977). Symptoms may be present at birth or appear weeks later and may continue for a period of time (Schardein 1993).

Diazepam in isolated doses is safe during labor (Briggs *et al.* 1998). There are conflicting reports on the effect of benzodiazepines on Apgar scores. Lowered Apgar scores have been reported with benzodiazepine use in some studies (Berdowitz *et al.* 1981; McElhatton 1994). One study found that diazepam reduced Apgar scores only when doses greater than 30 mg were administered during labor (Cree *et al.* 1973).

Breastfeeding

Neonates have limited capacity to metabolize diazepam (Morselli *et al.* 1973). Benzodiazepines are excreted in breast milk (Llewellyn and Stowe 1998). Because of the neonate's limited capacity to metabolize these drugs, they can accumulate and cause sedation, lethargy, and weight loss in the nursing infant. Although the extent to which benzodiazepines actually accumulate in the serum of breastfeeding infants is a matter of debate (Birnbaum *et al.* 1999), and three decades of studies support a low incidence of toxicity and adverse effects (Birnbaum *et al.* 1999; Llewellyn and Stowe 1998), caution regarding use of benzodiazepines while breastfeeding is advised.

Benzodiazepines and Risk of Accidental Injury

Another area of risk of benzodiazepine use relates to issues of psychomotor impairment resulting in injury. An examination of the medical records of a group of benzodiazepine users and nonusers found that the benzodiazepine users were more likely than nonusers to experience at least one episode of accident-related health care, to have a greater number of accident-related inpatient days, and to use significantly more non-accident-related health care services. Accident-related use of health care was most likely in the first month after the drug was prescribed (Oster *et al.* 1987). For older adults, the issue of benzodiazepine use increasing the risk for falls and fractures is of great concern because hip fractures are associated with increased morbidity and mortality. A number of studies (Boston Collaborative Drug Surveillance Program 1973; Cummings *et al.* 1995; Greenblatt *et al.* 1977; Hemmelgarn *et al.* 1997; Ray *et al.* 1992; Roth *et al.* 1980) have found a greater risk for falls with the use of long-half-life benzodiazepines, and others (Cumming and Klineberg 1993; Herings *et al.* 1995; Leipzig *et al.* 1999) have found the risk to be greater with short-half-life drugs. A more recent study (Wang *et al.* 2001) found the risk for hip fracture in older adults to be the same with the use of short-or long-half-life benzodiazepines. The researchers did find that the risk increased when benzodiazepine dosages were greater than 3 mg/day in diazepam equivalents. They also found the greatest risk to occur shortly after initiation of therapy and after 1 month of continuous use. A 5-year prospective cohort study following a large group of older adults newly exposed to benzodiazepines found that the risk of injury varied by benzodiazepine, independent of half-life, as did the risk associated with increasing dosage for individual agents (Tamblyn *et al.* 2005). Older adults using benzodiazepines were at greatest risk for a motor vehicle accident (Hemmelgarn *et al.* 1997). On the other hand, a study of the effect of New York State requiring triplicate forms for prescribing benzodiazepines showed that despite a 50% decrease in the number of prescriptions written, no significant change was seen in age-adjusted risk for hip fractures (Wagner *et al.* 2007).

Patients using benzodiazepines are nearly five times more likely than nonusers to experience a serious motor vehicle accident (Skegg *et al.* 1979). In the first 2 weeks after patients start to use benzodiazepines, there is a several-fold greater risk for hospitalization related to accidental injury compared with patients beginning to use antidepressants or antipsychotics (Neutel 1995).

The best protection from benzodiazepine-related injury is a discussion of these issues with patients before a benzodiazepine is prescribed. This discussion, including cautionary statements about driving or operating dangerous machinery, should be documented in the chart at the start of therapy. Patients should be educated about potentiation by alcohol or other sedating drugs. They also should be strongly advised never to abruptly discontinue the medicine because of a risk of seizures (Noyes *et al.* 1986), and the clinician's communication of this advice should be documented. Prescribing benzodiazepines for patients with a current or lifetime history of a substance use disorder should be done infrequently and only after a risk-benefit discussion is documented in the chart. It is good practice to routinely screen all patient for substance use disorders before prescribing a benzodiazepine and to document that this was done.

Benzodiazepine Use During the Coronavirus Disease 2019 (COVID-19) Pandemic

The COVID-19 pandemic was declared a national emergency in the United States on March 13, 2020. COVID-19 was linked to an increase in mental health problems, drug overdoses, and abuse of alcohol and controlled and illicit y (see

Holland *et al.* 2021 and de Dios *et al.* 2021). de Dios *et al.* (2021) studied the effect of the COVID-19 pandemic on the prescription-filling patterns for benzodiazepines and opioid drugs across 38 states from January 2019 to December 2020. When de Dios and colleagues compared the prescription patterns in the months before the pandemic declaration date (March 13, 2020) with those after that date, they found a statistically significant 2.0% increase in the proportion of all filled prescriptions for controlled substances that were benzodiazepine prescriptions and a 1.7% decrease in the proportion that were opioid prescriptions. Only the opioid prescription rate returned to predeclaration levels after May 18, 2020 (Milani *et al.* 2021). This report of an increase in benzodiazepine prescriptions is consistent with the findings of Jones *et al.* (2021), who reported that prescription rates returned to forecasted patterns in April-May 2020.

In a study of the records of approximately 15-17 million adults from 2018 through March 2021, Milani *et al.* (2021) found that the benzodiazepine prescription rate for women decreased 0.03% monthly from 2018 to January 2020, increased 0.06% monthly from January 2020 to April 2020, and then decreased 0.04% monthly from April 2020 to March 2021. For men there were no statistically significant changes in the slope of rates of benzodiazepine prescription over those same time periods. For individuals ages 65 years and older, the pattern was similar to that noted for women (Milani *et al.* 2021).

Conclusion

If given in adequate dosages, benzodiazepines are effective in the treatment of anxiety. They have a lower mortality and morbidity per million prescriptions than some of the alternatives (Girdwood 1974), including atypical antipsychotics. Benzodiazepines are quicker in onset of action, easier for the clinician to use, associated with better compliance, and less subjectively disruptive for the patient than any of the other medication alternatives. Until benzodiazepines are replaced by another class of medicine that is safer, better tolerated, and as rapidly effective, it is likely that they will continue to be prescribed to a significant proportion of patients.

CHAPTER 23

Buspirone

Donald S. Robinson, M.D.[++]
Karl Rickels, M.D.
Julie Farrington, M.D.

Altered central serotonergic function is implicated in several psychiatric disorders, especially mood and anxiety disorders. Discovery of the serotonin type 1A (5-HT_{1A}) receptor linked modulation of serotonin (5-hydroxytryptamine [5-HT]) neurotransmission to anxiety symptoms.

The notion of a role for serotonin in the treatment of anxiety arose from the finding that benzodiazepines reduce brain 5-HT turnover and that para-chlorophenylalanine (pCPA), an inhibitor of serotonin synthesis, mimics the effects of benzodiazepines in behavioral models of anxiety (Wise *et al.* 1972). Discovery of the 5-HT_{1A} receptor partial agonist buspirone confirmed that serotonin plays a key role in anxiolysis (Eison and Eison 1994). Because both benzodiazepines and buspirone reduce 5-HT impulse flow, albeit by different mechanisms, altered serotonergic tone was postulated to be an underlying factor in the etiology of anxiety disorders.

The 5-HT_{1A} Receptor

Identification of multiple serotonin receptors (Hoyer *et al.* 2002; Pierce *et al.* 2002) and discovery of the role of the 5-HT_{1A} receptor, which couples negatively to adenylyl cyclase (De Vivo and Maayani 1986; Savitz *et al.* 2009), led to pharmacological characterization of this receptor through the use of selective agonists (Hamon *et al.* 1984); selective partial agonist azapirones, such as buspirone (Figure 23-1); and specific antagonists (Fletcher *et al.* 1996). Clinical development of 5-HT$_{1A}$ partial agonists, which were active in models of both anxiety and depression, ensued when it became apparent that this receptor plays a central role in neuropsychiatric disorders (Robinson *et al.* 1989a).

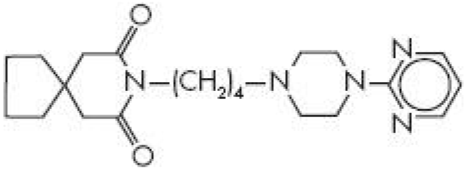

FIGURE 23-1. Chemical structure of buspirone.

Pharmacological and Clinical Implications

High regional density of 5-HT$_{1A}$ receptors in midbrain, hippocampus, and limbic areas comports with the notion that 5-HT neurotransmission modulates mood and anxiety. Brain regions with high densities of 5-HT$_{1A}$ receptors control thermoregulation, endocrine function, appetite, aggressive and sexual behavior, and mood. Mice lacking the 5-HT$_{1A}$ receptor gene exhibit anxious behavior (Parks *et al.* 1998; Pattij *et al.* 2002).

5-HT$_{1A}$ receptors on 5-HT neurons in midbrain raphe regions modulate release of 5-HT at synapses in forebrain. These somatodendritic autoreceptors control synthesis and impulse flow (Yocca 1990) and release (Sharp *et al.* 1989) of neurotransmitters from ascending 5-HT-containing neurons. Using the receptor-specific, tritiated ligand 8-hydroxy-2-[*N*-dipropylamino]-tetralin (8-OH-DPAT), Stockmeier *et al.* (1998) reported increased binding of the ligand to inhibitory 5-HT$_{1A}$ autoreceptors in the dorsal raphe of suicide victims, in support of the hypothesis that these people had diminished 5-HT neuronal activity. Imaging studies of brain regions using 8-OH-DPAT or the receptor-specific radioligand [carbonyl-

^{11}C]WAY-100635 confirmed diminished function (reduced binding potential) of serotonin 5-HT$_{1A}$ receptors in the brains of both suicide victims and patients with major depressive disorder (MDD) compared with matched control subjects (Boldrini *et al.* 2008; Drevets *et al.* 2007; Hirvonen *et al.* 2008; Meltzer *et al.* 2004), indicating diminished activity of 5-HT neurons in mood disorders. Blunted 5-HT$_{1A}$ receptor-mediated response to corticosteroids is present in patients with MDD, suggesting desensitization of these receptors in patients with anxiety and depression (Lesch 1992; Rausch *et al.* 2006; Stahl 1992).

5-HT Receptors and Partial Agonists

Given the evidence implicating 5-HT in mood disorders and the role of the 5-HT$_{1A}$ receptor in 5-HT neurotransmission, drugs targeting this receptor hold interest for the treatment of mood and anxiety disorders. Partial agonists of this receptor act in part by signal attenuation at one or more target receptors (Yocca and Altar 2006). The partial agonist buspirone produces a therapeutic response with an excellent safety profile and was developed for the treatment of anxiety and associated depression.

The selective 5-HT$_{1A}$ receptor partial agonist gepirone received FDA approval for the treatment of MDD in 2016 but only very recently (2023) reached the market for that indication. Gepirone extended-release (ER) has also been shown to have anxiolytic properties (Kaur Gill *et al.* 2019; Pecknold *et al.* 1993) and is in Phase III trials for generalized anxiety disorder (GAD) and hypoactive sexual desire disorder (FabreKramer Pharmaceuticals 2023). Other azapirones include tandospirone, ipsapirone, and lesopitron. There has been one completed trial of tandospirone in GAD, but there are currently no published findings.

History and Development

Buspirone hydrochloride, an azaspirodecanedione derivative (Wu *et al.* 1969), is a dopamine autoreceptor and D$_3$ receptor antagonist and partial agonist at 5-HT_{1A} receptors. It was originally studied as a putative antipsychotic agent but was not efficacious (Sathananthan *et al.* 1975). Until subsequent discovery of buspirone's high-affinity binding to the newly discovered 5-HT_{1A} receptor, the anxiolytic activity of buspirone was presumed to be dopaminergic.

A Phase II proof-of-concept study of patients with DSM-II (American Psychiatric Association 1968) anxiety disorder showed significant anxiolytic efficacy of buspirone compared with placebo (Goldberg and Finnerty 1979), which fostered its clinical development as an antianxiety agent (Robinson 1991). Later, buspirone was found to bind to dopamine D_3 and D_4 receptors, suggesting its possible utility in the treatment of drug addiction (Bergman *et al.* 2013; Le Foll and Boileau 2013).

Pharmacological Profile

Buspirone has low affinity in vitro for noradrenergic, cholinergic, and histaminergic receptors, and it does not displace [^{3}H] diazepam or [^{3}H] nitrazepam from the benzodiazepine receptor complex (Riblet *et al.* 1982). Although buspirone displaces [^{3}H] spiperone from rat striatal membranes at high concentrations (Mennini *et al.* 1986, 1987), dopamine receptor binding appears to play no role in either the therapeutic effects or the side effects of buspirone (Eison *et al.* 1991). In the frontal cortex of freely moving rats, buspirone produces dose-dependent decreases in dialysate levels of 5-HT and increases in levels of dopamine and norepinephrine, findings indicative of multiple mechanisms by which buspirone may modify monoaminergic neurotransmission (Gobert *et al.* 1999).

The discovery that nanomolar quantities of buspirone displaced [^{3}H]5-HT from hippocampal membranes (Glaser and Traber 1983) led to elucidation of buspirone's actions on specific central 5-HT receptors. Buspirone inhibits [^{3}H]5-HT binding to cortical and hippocampal membranes (Skolnick *et al.* 1985) and selectively displaces [^{3}H]8-OH-DPAT from 5-HT_{1A} receptor-binding sites in rat hippocampal membranes with high affinity (24 nM) (Yocca 1990).

The antianxiety properties of buspirone reflect its actions at both presynaptic and postsynaptic 5-HT_{1A} receptors (Eison and Eison 1994; Yocca 1990). At presynaptic 5-HT_{1A} receptors in the dorsal raphe, buspirone acts as a full agonist, inhibiting neuronal 5-HT synthesis and firing, whereas at postsynaptic receptors in hippocampus and cortex it functions as a partial agonist.

Buspirone differs from benzodiazepines in that it does not inhibit motor coordination or spontaneous motor activity but can produce serotonin syndrome in rats (Barrett and Witkin 1991; Eison *et al.* 1991). Unlike benzodiazepines, buspirone lacks abuse potential and does not impair psychomotor performance alone or in combination with ethanol (Griffith *et al.* 1986; Smiley 1987; Sussman and Chow 1988). The behavioral effects of buspirone and benzodiazepines differ somewhat in animal models of anxiety (Barrett and Witkin 1991) in that buspirone does not uniformly increase punished or conflict responding in rats and monkeys. In pigeons, by contrast, buspirone

increases punished response equivalently to benzodiazepines, a characteristic of 5-HT_{1A} receptor agonists such as 8-OH-DPAT, whereas tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), opioids, antipsychotics, and psychomotor stimulants do not. Like benzodiazepines, buspirone increases exploratory and social interaction behavior in rodents. It also has been shown to decrease the exaggerated freezing response in a mouse model of PTSD-like symptoms (Malikowska-Racia *et al.* 2020).

5-HT_{1A} agonists are active in animal models of depression. Similar to tricyclic antidepressants and SSRIs, 5-HT_{1A} agonists such as 8-OH-DPAT and the azapirones produce antidepressant-like behavior in the forced-swim test in rats (Wieland and Lucki 1990). This effect occurs in the absence of changes in locomotor activity and is not diminished by pretreatment with the 5-HT synthesis inhibitor pCPA, suggesting that 5-HT_{1A} agonists produce an antidepressant response through postsynaptic effects on 5-HT_{1A} receptors. Buspirone's activity in preclinical models of depression comports with findings in placebo-controlled trials of buspirone indicative of its antidepressant properties (Rickels *et al.* 1991; Robinson *et al.* 1989a). The buspirone metabolite 1-(2-pyrimidinyl)piperazine (1-PP) lacks such activity.

Pharmacokinetics and Mechanism of Action

With oral administration, buspirone undergoes extensive first-pass metabolism by cytochrome P450 3A4 enzymes, with a mean elimination half-life of 3-4 hours (Gammans and Johnston 1991). Food prolongs the elimination half-life of buspirone, as does hepatic or renal impairment. The pharmacokinetics of buspirone in older adults and young adults do not differ (Gammans *et al.* 1989).

Buspirone has several metabolites with differing pharmacological activity: 6-hydroxybuspirone (6-OH-Bu), 5-hydroxybuspirone, 8-hydroxybuspirone, and 1-PP. Noradrenergic properties of 1-PP may induce unwanted side effects in patients who have panic attacks or are undergoing benzodiazepine withdrawal. Conversion of buspirone to 6-OH-Bu is the major metabolic pathway in the hepatic clearance of buspirone (Dockens *et al.* 2006; Zhu *et al.* 2005), and bioavailability of 6-OH-Bu is greater than that of the parent drug (19% vs. 1.4% for buspirone [Wong *et al.* 2007]), significantly contributing to buspirone's therapeutic activity (Dockens *et al.* 2006). In vitro, 6-OH-Bu exhibits high affinity (25 nM) and partial agonist activity for the 5-HT_{1A} receptor (Wong *et al.* 2007).

The anxiolytic effects of buspirone appear to be mediated by its actions on 5-HT receptors in the limbic system (Eison and Eison 1994; Yocca 1990). In addition to being a 5-HT_{1A} agonist, buspirone acts as both a D_2 agonist and a D_2 antagonist in the anterior pituitary, regulating prolactin levels. Buspirone has significant neuroendocrine effects beyond those related to dopamine receptors. 5-HT_{1A} receptors regulate the neuroendocrine hormones, including growth hormone, adrenocorticotropic hormone, corticosterone, and oxytocin (Gilbert *et al.* 1988; Pan and Gilbert 1992; Van de Kar *et al.* 1985; Vicentic *et al.* 1998). Buspirone produces dose-dependent increases in rat plasma prolactin levels (Meltzer and

Fleming 1982). Buspirone antagonizes the inhibitory effects of dopamine on prolactin release from the rat pituitary gland in vitro, illustrative of its partial agonist activity at D_2 receptors (Meltzer *et al.* 1991). All azapirones decrease body temperature (Cowen *et al.* 1990; Meltzer *et al.* 1991). Buspirone stimulation of prolactin and corticosterone secretion in the rat is increased by pCPA, whereas spiperone inhibits buspirone-induced increases in corticosterone secretion (Meltzer *et al.* 1991). Pindolol, a 5-HT_{1A} antagonist, does not block the buspirone-induced increase in prolactin (Meltzer *et al.* 1991). The neuroendocrine effects of buspirone are complex, reflecting properties of both dopamine antagonism and 5-HT_{1A} partial agonism.

Indications and Efficacy

Approved Clinical Indications

Generalized Anxiety Disorder

Clinical development of buspirone began after positive findings were reported in a placebo-controlled proof-of-concept study of anxious patients (Goldberg and Finnerty 1979). In Phase III placebo-controlled trials comparing buspirone and diazepam, the two anxiolytics had comparable efficacy for patients meeting diagnostic criteria for DSM-II anxiety neurosis (Bohm *et al.* 1990a; Goldberg and Finnerty 1982; Rickels *et al.* 1982). Currently, buspirone is FDA approved for the short-and long-term treatment of GAD and short-term symptomatic relief of anxiety.

Buspirone has a slower onset of therapeutic effect than the benzodiazepines (Enkelmann 1991; Pecknold *et al.* 1989; Rickels 1990). This slower onset is attributable to differences between buspirone and benzodiazepines in relief of somatic anxiety, whereas the two drugs are similar in rates of alleviation of psychic anxiety. Lack of sedation with buspirone also contributes to the perception of a more gradual onset of anxiolysis, similar to that with imipramine (Rickels *et al.* 1993) and SSRIs (Rickels *et al.* 2003). With buspirone, relief of somatic anxiety (particularly insomnia) occurs only after psychic anxiety symptoms abate, whereas the immediate sedating properties of benzodiazepines give the perception of a faster onset of therapeutic benefit.

A 6-month double-blind comparative trial of buspirone and benzodiazepines confirmed that onset of anxiolytic effects was slower with buspirone than with clorazepate during the first 4 weeks of treatment (Rickels *et al.* 1988). With ongoing treatment, however, the therapeutic response to the two drugs was equivalent. Clinical improvement was maintained over the 6-month study period, and therapeutic tolerance did not develop with either drug. On double-blind termination of treatment at 6 months, several patients who stopped clorazepate abruptly experienced relapse, whereas none relapsed in the buspirone group. The finding that symptom relapse did not occur with abrupt discontinuation of buspirone confirmed conclusions from other investigators (Fontaine *et al.* 1984; Noyes *et al.* 1988) that the rapid return of symptoms after discontinuation of clorazepate was attributable to benzodiazepine withdrawal rather than to a recrudescence of the underlying anxiety disorder.

A benzodiazepine may be indicated as initial therapy for chronically anxious patients; however, longer-term benzodiazepine treatment can lead to physical dependence. Benzodiazepine treatment may be inappropriate for some patients because of the risk of substance abuse or cognitive impairment. When a patient is starting buspirone treatment, one should inform the patient that the drug is less sedating and has a

gradual onset of action. Patients can be reassured that buspirone lacks physical dependence potential and does not impair cognition or acquisition of coping skills (Rickels and Schweizer 1990).

Possible clinical benefits of buspirone in benzodiazepine withdrawal syndrome were assessed in 15 patients with chronic anxiety who had previously attempted both abrupt and gradual withdrawal of benzodiazepine treatment without success (Schweizer and Rickels 1986). In this study, addition of buspirone overlapping with tapering of the benzodiazepine dosage did not ameliorate the symptoms of benzodiazepine withdrawal, and no patient could be maintained on buspirone monotherapy after complete withdrawal of benzodiazepine treatment. In other studies, buspirone showed only modest beneficial effects on benzodiazepine withdrawal syndrome (Delle Chiaie *et al.* 1995; DeMartinis *et al.* 2000; Udelman and Udelman 1990).

After buspirone's approval by the FDA, several well-controlled efficacy trials in GAD confirmed the drug's significant anxiolytic efficacy (Enkelmann 1991; Laakmann *et al.* 1998; Lader and Scotto 1998; Murphy *et al.* 1989; Pecknold *et al.* 1989; Scheibe 1996). In a 3-week placebo-controlled comparison trial of 60 patients with anxiety disorder in a general medical setting, Bohm *et al.* (1990a) found buspirone and the benzodiazepine clobazam to be equally effective and superior to placebo in relieving anxiety.

Long-term follow-up at 40 months of patients who previously completed a 6-month controlled trial comparing buspirone and clorazepate revealed that none of the buspirone-treated patients needed anxiolytic medication, whereas more than 50% of the patients treated with clorazepate needed continuation anxiolytic therapy (Rickels and Schweizer 1990).

Case studies support the efficacy of buspirone in treating anxiety in genetic disorders. GAD responded to buspirone in three cases of young adults with Williams's syndrome (Thom *et al.* 2020). Another series of three case studies found a decrease in behaviors attributed to anxiety with buspirone in the neurogenetic disorder Angelman's syndrome (Balaj *et al.* 2019). In all six cases, buspirone was well tolerated and produced sustained response.

Buspirone was not found beneficial in anxiety associated with chemotherapy. In a randomized, placebo-controlled trial of 432 patients, no significant reduction in dyspnea or anxiety in patients with cancer was found (Peoples *et al.* 2016).

Strawn *et al.* (2018) conducted a review and Bayesian analysis of abandoned randomized controlled trials (RCTs) assessing buspirone in youths with anxiety. They found buspirone treatment to be well tolerated in pediatric patients with GAD, although two RCTs were underpowered to detect small effect sizes (Cohen's $d < 0.15$). Strawn and colleagues proposed that Bayesian approaches may facilitate reexamination of data from abandoned clinical trials.

Buspirone was evaluated in older adults with anxiety symptoms in a double-blind, placebo-controlled trial and was found to be both safe and effective (Bohm *et al.* 1990b). Buspirone's lack of sedation and sparing of cognition and memory were strong therapeutic advantages for this population. Meta-analyses of several multicenter trials of buspirone in older adults also showed buspirone to be safe and well tolerated (Ritchie and Cox 1993; Robinson *et al.* 1988).

Buspirone treatment also was assessed in patients with panic disorder in placebo-controlled trials (Pohl *et al.* 1989; Sheehan *et al.* 1990). Buspirone does not diminish

panic attacks. However, a meta-analysis of double-blind three-arm multicenter trials in panic disorder comparing buspirone, imipramine, and placebo found that both imipramine and buspirone reduced anxiety symptoms (Robinson *et al.* 1989b). Buspirone's lack of effect on the number of panic attacks is unsurprising in light of preclinical evidence that buspirone increases firing rates in the locus coeruleus (Eison and Temple 1986) and causes noradrenergic hyperactivity (Sanghera *et al.* 1982), both manifestations of panic disorder.

Mixed Anxiety-Depression

In initial trials of patients with anxiety disorder and subsyndromal depression, depressive symptoms decreased significantly with buspirone treatment (Feighner *et al.* 1982; Goldberg and Finnerty 1979). This finding fostered interest in the potential antidepressant properties of buspirone because of the high comorbidity of GAD and MDD (Brown and Barlow 1992) and led to speculation that GAD and MDD may be differing clinical manifestations of a single underlying diathesis. Genetic studies of patients with MDD and GAD suggested that genetic vulnerability for the two disorders is largely shared (Kendler *et al.* 1992). The relationship between

MDD and GAD and its implications for their clinical treatment have been reviewed (Kendler *et al.* 1992; Roy-Byrne 2008).

Buspirone treatment of patients with MDD associated with significant anxiety symptoms was assessed in placebo-controlled trials (Rickels *et al.* 1991; Robinson *et al.* 1989a, 1990). Patients with MDD were eligible for inclusion in these studies if their Hamilton Rating Scale for Depression (Hamilton 1960) and Hamilton Anxiety Scale (Hamilton 1959) scores were [?] 18 and [?] 15, respectively. The daily dosage ranged up to a maximum of buspirone 90 mg/day (mean [?] 50 mg/day). Buspirone treatment was superior to placebo, with a global response rate (based on Clinical Global Impression-Improvement scale scores) of 70% for buspirone and 35% for placebo (Rickels *et al.* 1991). In a subsequent placebo-controlled study involving 177 geriatric depressed outpatients, Schweizer *et al.* (1998) compared buspirone and imipramine treatment for 8 weeks. There was a statistically significant treatment effect for both buspirone (mean daily dosage [?] 50 mg) and imipramine (mean daily dosage [?] 90 mg) compared with placebo treatment.

Buspirone augmentation of SSRI treatment of partially responding depressed patients leads to further improvement (Dimitriou and Dimitriou 1998; Jacobsen 1991; Landen *et al.* 1998). These findings were confirmed in a report of the Sequenced Treatment Alternatives to Relieve Depression program. Patients who initially did not respond to an adequate therapeutic trial with an SSRI responded when their medication was augmented with either buspirone or bupropion (Trivedi *et al.* 2006). In an exploratory double-blind, placebo-controlled study of patients with an MDD diagnosis, Fava *et al.* (2012) reported significant antidepressant efficacy for combined buspirone 15 mg and melatonin slow release 3 mg. This preliminary finding is mentioned only to indicate ongoing interest in buspirone as a potential augmenter of other antidepressants, not as a treatment recommendation.

Nonapproved Clinical Indications

Potential clinical indications for buspirone treatment unapproved by the FDA were reviewed by Rickels *et al.* (2003); selected studies are mentioned here.

Gastrointestinal Related Disorders

An RCT found buspirone ineffective for patients with functional dysphagia and ineffective esophageal motility compared with placebo (Aggarwal *et al.* 2018). Case studies reported by Caviglia *et al.* (2017) found that patients with functional dyspepsia who did not respond to first-line therapy and reported meal-related discomfort may benefit from buspirone or amitriptyline-based therapies. A single case study of a 14-year-old found efficacy for buspirone in avoidant/restrictive food intake secondary to fear of emesis (Okereke 2018).

Substance-Related Disorders

Several placebo-controlled trials have demonstrated the usefulness of buspirone in facilitating smoking cessation (Hilleman *et al.* 1992; West *et al.* 1991), although its main effect was in smokers who were also highly anxious (Cinciripini *et al.* 1995).

Buspirone has been assessed in several double-blind, placebo-controlled trials involving anxious outpatients with coexisting alcohol use disorder and found to be efficacious (Rickels *et al.* 2003). Buspirone's lack of abuse potential and negligible additive effects on psychomotor and cognitive functions when coadministered with alcohol (Mattila *et al.* 1982) make it a useful addition to pharmacotherapies for alcohol-related disorders.

Buspirone was found to ameliorate symptoms of opioid withdrawal in a placebo-controlled trial (Buydens-Branchey *et al.* 2005). A subsequent study used an animal model investigating morphine reward. Coadministration of buspirone prevented the rewarding effects of morphine and its effects on the metabolism of dopamine and serotonin in the nucleus accumbens and caudate nucleus in rat striatum. The authors suggested that 5-HT$_{1A}$ receptor-dependent modulation of dopamine neurotransmission in the caudate nucleus and nucleus accumbens is involved in modulation of the rewarding effects of morphine in buspirone cotreated animals, documenting an important role of 5-HT$_{1A}$ receptors in drug addiction (Haleem *et al.* 2018).

Although elevations in synaptic dopamine levels have been demonstrated to play a pivotal role in the reinforcing effects of cocaine, neither D_1 nor D_2 receptor antagonists have proved clinically effective in cocaine addiction. Speculating that dopamine D_3 and D_4 receptors might be possible targets for pharmacotherapy, Bergman *et al.* (2013) undertook an investigation of buspirone, which has been found to bind with high affinity to these receptors, to evaluate its functional effects in animal models. On the basis of their finding that buspirone produced a downward shift in the dose-effect function for cocaine-maintained behavior, Bergman *et al.* proposed that buspirone be evaluated for its utility in the management of cocaine addiction. However, in a 16-week double-blind multicenter pilot trial, Winhusen *et al.* (2014) found that buspirone at dosages titrated up to 60 mg/day was not beneficial in preventing relapse to cocaine use. An RCT found buspirone was not effective in intranasal methamphetamine use disorder (Reynolds *et al.* 2017). Another study found buspirone exerts inhibitory effects on psilocybin-induced effects, presumably via 5-HT_{1A} receptor activation, an interaction between 5-HT_{1A} and 5-HT_{2A} receptors, or both (Pokorny *et al.* 2016).

In a related application, an animal model study found that effects of morphine plus buspirone and baclofen plus buspirone had an additive effect on decreasing schedule-controlled response, suggesting a role for buspirone as an augmenting agent in

pain control. Effects of the two combinations produced synergistic thermal antinociception. Naltrexone and CGP35348 antagonized the effects of morphine and baclofen, respectively (Wilkerson *et al.* 2019).

Adjunctive Use in Schizophrenia

Several studies have evaluated the adjunctive use of buspirone in patients with chronic schizophrenia being treated with typical and atypical antipsychotic drugs. In a 6-month placebo-controlled trial of adjunctive buspirone 30 mg/day in patients taking an atypical antipsychotic maintenance drug, Sumiyoshi *et al.* (2007) observed no improvement in

Brief Psychiatric Rating Scale scores, although they noted improved recall on one secondary outcome measure, the Verbal Learning subscale. Two placebo-controlled pilot trials of limited size by an Iranian group found that adjunctive treatment with buspirone improved negative symptoms in patients with chronic schizophrenia taking antipsychotic maintenance drugs (Ghaleiha *et al.* 2010; Sheikhmoonesi *et al.* 2015). Wang *et al.* (2019) conducted an RCT examining buspirone's effects on cognitive function in patients with schizophrenia treated with atypical antipsychotic drugs. Repeated-measures analysis of variance showed significant differences between the group receiving buspirone cotreatment and the group receiving atypical antipsychotics alone in their arithmetic, similarities, picture completion, block design, Social Disability Screening Schedule, and Family Burden Interview Schedule scores ($P < 0.05$), but no difference was found with regard to the information, digit span test, or digit symbols scores ($P > 0.05$). The authors concluded that cotreatment with buspirone and atypical antipsychotic drugs outperformed atypical antipsychotic drugs alone in improving cognitive deficit and reducing family burden of schizophrenia (Wang *et al.* 2019). A meta-analysis conducted by two investigators systematically and independently searched English and Chinese databases for adjunctive use of buspirone and tandospirone in schizophrenia treatment. There was no efficacy for psychotic symptoms, but they did find that adjunctive buspirone may be associated with improvement in cognitive deficits in schizophrenia and extrapyramidal symptoms (Zheng *et al.* 2018). Higher-quality RCTs are needed to confirm these findings.

Adjunctive Use in Autism Spectrum Disorder

Buspirone treatment has been assessed in patients with autism spectrum disorder (ASD). In an 8-week placebo-controlled trial of adjunctive buspirone during risperidone maintenance treatment of 40 children and adolescents with ASD, Ghanizadeh and Ayoobzadehshirazi (2015) observed a 30% decline in Irritability subscale scores on the Aberrant Behavior Checklist-Community rating scale in 13 of the 16 patients taking buspirone versus 7 of the 18 patients in the placebo group, a significant treatment effect. In a three-arm, 24-week placebo-controlled trial (n = 166), Chugani *et al.* (2016) assessed the safety and efficacy of low-dosage buspirone for children with ASD. The buspirone 2.5 mg bid group showed significant improvement in irritability ratings, whereas the 5.0 mg bid group did not differ from the placebo group. In a randomized double-blind study, buspirone was as effective as methylphenidate in treating aggressive behavior in ADHD (Davari-Ashtiani *et al.* 2010). A retrospective chart review of buspirone treatment for anxiety in ASD also supported efficacy (Ceranoglu *et al.* 2019). However, Matsui *et al.* (2016) performed a meta-analysis of RCTs and single-arm trials published before October 27, 2015, with the conclusion that it remains unclear whether buspirone use has benefit for patients with ADHD.

Other Disorders

Buspirone's utility has been explored in a variety of other disorders. In a placebo-controlled study, Lee *et al.* (2005) found beneficial effects from buspirone in patients with migraine and anxiety symptoms. Buspirone was evaluated under double-blind conditions in Alzheimer's disease patients with aggressive behavior and agitation (Cantillon *et al.* 1996) and was found to be superior to haloperidol. In a retrospective study of patients from a geropsychiatric outreach program who had behavioral disturbance due to dementia, buspirone was effective at a mean dosage of 25.7 mg +-12.50 (Santa Cruz *et al.* 2017). Four RCTs have addressed buspirone use in female sexual interest/arousal disorder, finding efficacy as a function of etiology (Tuiten *et al.* 2018a, 2018b). Three case studies reported response to buspirone for sleep bruxism in children. One case involved primary sleep bruxism in a 7-year-old boy (Saglam *et al.* 2019), and the other two involved sleep bruxism associated with fluoxetine therapy (Akbas and Bilgic 2018; Colak Sivri and Akca 2016). Lastly, studies in animal models and clinical trials indicated that buspirone may be useful in treating tardive dyskinesia (Howland 2011) and L-dopa-induced and graft-induced dyskinesias of Parkinson's disease (Loane and Politis 2012).

Dosage and Administration

Buspirone is available as immediate-release tablets in strengths of 5 mg, 7.5 mg, 10 mg, 15 mg, and 30 mg. The recommended buspirone dosage for treatment of GAD is 15-20 mg/day initially, prescribed in divided doses, with increases to 30 mg/day if indicated and a maximum dosage of 60 mg/day. It should be mentioned that in the double-blind, placebo-controlled MDD trials described earlier (see the section "Mixed Anxiety-Depression"), the maximum dosage was 90 mg/day (Rickels *et al.* 1991; Robinson *et al.* 1989a, 1990). Therefore, higher buspirone dosages than those prescribed for anxiety disorders may be needed in the treatment of MDD, either as monotherapy or as augmentation of an SSRI.

Therapeutic response to buspirone differs in anxious patients naive to benzodiazepine treatment compared with patients recently treated with a benzodiazepine (DeMartinis *et al.* 2000; Schweizer and Rickels 1986). Findings of placebo-controlled efficacy trials showed that patients with GAD with either no prior benzodiazepine treatment or temporally remote benzodiazepine treatment (> 6 months previously) experienced greater improvement with buspirone therapy than did patients who either were currently receiving or had recently completed treatment with a benzodiazepine. This lower therapeutic response may reflect a subclinical benzodiazepine withdrawal syndrome (possibly exacerbated by buspirone's 1-PP metabolite). Directly switching from SSRI treatment to buspirone is not problematic.

Side Effects and Toxicology

Summarizing data from 17 clinical trials, Newton *et al.* (1986) noted the incidence of frequently reported adverse effects experienced during buspirone treatment: dizziness

(12%), drowsiness (10%), nausea (8%), headache (6%), nervousness (5%), fatigue (4%), insomnia (3%), light-headedness (3%), dry mouth (3%), and excitement (2%). A literature review of movement disorder symptoms associated with buspirone in 2020 revealed 14 cases of dyskinesia, 10 cases of akathisia, 8 cases of myoclonus, 6 cases of Parkinsonism, and 6 cases of dystonia. Cases not clearly defined were 7 cases of tension, 14 cases of incoordination, and several cases of dyskinesia, tics, and Parkinsonism (Rissardo and Caprara 2020). A case of stiff person syndrome correlated with initiation of buspirone was also reported (Sablaban and Prabhakar 2017). A case report of serotonin syndrome (Nunes and Botas 2020) included buspirone in the regimen of prescribed serotonergic medications. Buspirone lacks abuse potential, unlike alcohol and the benzodiazepines (Balster 1991). Psychomotor function studies, including evaluation of complex motor driving skills and memory tasks, have documented buspirone's lack of impairment potential in these domains (Boulenger *et al.* 1989; Greenblatt *et al.* 1994; Lucki *et al.* 1987; Smiley and Moskowitz 1986). Buspirone does not inhibit cytochrome P450 enzymes, although it does cause modest elevations of haloperidol and cyclosporin A levels. Buspirone has few significant pharmacodynamic interactions with other psychotropic drugs, apart from a potential risk of serotonin syndrome in combination with monoamine oxidase inhibitors. Since buspirone was introduced into clinical medicine, no deaths attributable solely to buspirone overdose have been reported. Buspirone remains an unusually safe and well-tolerated anxiolytic with no abuse potential.

Conclusion

Discovery of the 5-HT$_{1A}$ receptor was instrumental in linking modulation of 5-HT neurotransmission with anxiety disorders. Buspirone, a selective partial agonist of the 5-HT$_{1A}$ receptor, is the only drug in this class of antianxiety agents approved for the treatment of GAD and anxiety with associated depressive symptoms.

CHAPTER 24

Brexanolone and Other Neurosteroids

Riah Patterson, M.D.
Holly Krohn, M.P.H.
Samantha Meltzer-Brody, M.D., M.P.H.

History and Discovery

Reproductive steroids play a powerful role in the regulation of most systems that have been implicated in the etiology and pathogenesis of depression and specifically postpartum depression (PPD). They interact with the receptors and enzymes (metabolic and synthetic) of almost all neurotransmitters, including serotonin, dopamine, norepinephrine, glutamate, and g-aminobutyric acid (GABA) (Rubinow *et al.* 1998; Schiller *et al.* 2020). There has been great interest in understanding the role of GABA and, in particular, the disturbance of GABAergic inhibition, which plays a vital regulatory role in neuronal activity and circuits (Lee and Maguire 2014). Importantly, allopregnanolone, a neurosteroid that is the metabolite of the reproductive hormone progesterone, is a potent activator of GABA receptors, regulating their subunit composition and contributing to tonic inhibition.

Evidence demonstrating the role of allopregnanolone as an activator of GABA receptors comes from animal model work demonstrating that genetically induced interference (deficient in the GABA$_A$ receptor [GABA$_A$R] delta subunit or KCC2) with GABA receptor signaling created a mouse model of PPD (Maguire and Mody 2008), which was subsequently reversed by administration of allopregnanolone (Melon *et al.* 2018a, 2018b). In addition, animals with genetically induced GABA deficits showed abnormal activation of neural networks (prefrontal cortex and amygdala), which was repaired after administration of allopregnanolone (Melon *et al.* 2018a).

It is important to note that neuroactive steroids, such as allopregnanolone, represent a class of GABA$_A$R positive allosteric modulators (PAMs) that are pharmacologically distinct from benzodiazepines (Meltzer-Brody and Kanes 2020). Benzodiazepines act at

the synaptic level only (Sigel and Buhr 1997; Sigel and Ernst 2018), in contrast to neuroactive steroids such as allopregnanolone, which act at both synaptic and extrasynaptic GABA$_A$Rs (Abramian *et al.* 2014; Laverty *et al.* 2017; Sigel and Ernst 2018).

Clinical Trials of Brexanolone

Open-Label Study

Preclinical animal studies served as the rationale for the initial open-label trial of a proprietary formulation of allopregnanolone, brexanolone, for women with PPD. The preclinical data indicated that the rapid changes in levels of allopregnanolone in the transition from pregnancy to the postpartum period could trigger PPD in some women. Therefore, brexanolone (USAN; formerly SAGE-547 Injection), a proprietary, intravenous form of allopregnanolone, was studied as a potential treatment for severe PPD in an open-label study in 2015 (Kanes *et al.* 2017a). The initial four women who participated in the open-label study at one study site demonstrated a robust treatment response. All of the women enrolled had severe PPD (onset of symptoms in the early postpartum period), defined as a 17-item version of the Hamilton Rating Scale for Depression (Ham-D-17) score of [?] 20. The brexanolone was titrated over 12 hours to reach third-trimester allopregnanolone levels. After a 36-hour maintenance infusion, tapering occurred over 12 hours (Kanes *et al.* 2017a). The drug was well tolerated, and given that all four women showed a reduction in Ham-D scores consistent with remission of symptoms, the open-label trial was concluded and a multisite double-blind trial was begun (Kanes *et al.* 2017a).

Phase II Double-Blind Study

The Phase II double-blind, randomized, placebo-controlled trial (ClinicalTrials.gov number NCT02614547) maintained the same protocol as the initial open-label trial and was conducted from 2015 to 2016 (Kanes *et al.* 2017b). In the Phase II study, 21 women with severe PPD (Ham-D score [?] 26) who were [?] 6 months postpartum were recruited. Patients in the trial were recruited from four hospitals in the United States and randomly assigned (1:1) by computer to receive either brexanolone or placebo. The study drug (either brexanolone or placebo) was administrated as a continuous intravenous infusion over 60 hours. Both the investigators and the patients were blinded to treatment arm. The primary endpoint was Ham-D change from baseline at the 60-hour mark. All patients in the trials were followed for 1 month until day 30 (Kanes *et al.* 2017b).

Of the 21 women recruited into the study, 10 women were randomly assigned to receive brexanolone and 11 women received placebo. At the 60-hour primary endpoint assessment, the Ham-D mean reduction from baseline was 21.0 (standard error [SE] 2.9) in those receiving brexanolone, compared with an 8.8 point (SE 2.8) reduction in those receiving placebo (difference [?] 12.2, 95% CI, [?] 20.77 to [?] 3.67; $P = 0.0075$; effect size 1.2). There were no study discontinuations due to serious adverse events and no deaths. The most commonly reported side effects in the brexanolone group were dizziness and sleepiness (Kanes *et al.* 2017b).

Overall, the findings from the Phase II trial were encouraging and supported further development of brexanolone as a potential new treatment for PPD. The findings in the Phase II study led to initiation of the Phase III studies of brexanolone.

Phase III Double-Blind Studies

The Phase III trials consisted of two double-blind, randomized, placebo-controlled trials conducted at more than 30 clinical sites in the United States (ClinicalTrials.gov numbers NCT02942004 [study 1] and NCT02942017 [study 2]). Inclusion criteria were as follows: women who were 18-45 years old and within 6 months postpartum at the initial screening visit. Those enrolled demonstrated severe PPD (Ham-D score [?] 26) for one of the Phase III trials and a Ham-D score of 20-25 for the second study. Women with histories of psychosis, bipolar disorder, schizophrenia, schizoaffective disorder, or renal failure were excluded. Women enrolled in the study were randomly assigned (1:1:1) to receive either a 60-hour intravenous infusion of brexanolone 90 mg/kg/hour (BRX90), brexanolone 60 mg/kg/hour (BRX60), or placebo. Both the investigators and the patients were blinded to study treatment arm (Meltzer-Brody *et al.* 2018).

The study was conducted from August 2016 through October 2017 for both Phase III studies. Of the 375 women screened for study participation, 138 were randomly assigned in the first study to receive either BRX90 (n = 45), BRX60 (n = 47), or placebo (n = 46), and 108 women were randomly assigned in the second study to receive BRX90 (n = 54) or placebo (n = 54).

In the first study, at the 60-hour primary endpoint, the least-squares mean reduction in Ham-D score compared with baseline was 19.5 points (SE 1.2) in the BRX60 group, 17.7 points (SE 1.2) in the BRX90 group, and 14.0 points (SE 1.1) in the placebo group ([?] 5.5 [95% CI, [?] 8.8 to [?] 2.2], P = 0.0013 in the BRX60 group and 3.7 [95% CI, [?] 6.9 to [?] 0.5], P = 0.0252 in the BRX90 group). In the second study at the 60-hour primary endpoint, the least-squares mean reduction in Ham-D score compared to baseline was 14.6 points (SE 0.8) in the BRX90 group and 12.1 points (SE 0.8) in the placebo group ([?] 2.5 [95% CI, [?] 4.5 to [?] 0.5], P = 0.0160). The most common adverse events in the brexanolone groups were headache, dizziness, and sleepiness (Meltzer-Brody *et al.* 2018).

The findings of the Phase III studies demonstrated a clinically meaningful reduction in Ham-D scores that was statistically significant (Meltzer-Brody *et al.* 2018). The rapid onset of action and sustained treatment response over the 30-day study period suggested that brexanolone is a novel pharmacological treatment for PPD that could improve treatment options for women with this often severe disorder.

In sum, the development of a proprietary, intravenous form of allopregnanolone (brexanolone) as a first-in-class pharmacotherapy led to the 2019 approval by the FDA for the treatment of women with PPD. There was a 5-year period of time between the first open-label infusion of brexanolone (2015) and FDA approval of brexanolone in March 2019. The accelerated development timeline of the first approved drug for PPD and the first in its class was an exciting step forward for the field.

Structure-Activity Relations

Brexanolone is an aqueous mixture of synthetic allopregnanolone ($C_{21}H_{34}O_2$, 3a,5a-THP with a relative molecular mass of 318.5 Da) and the solubilizing agent sulfobutyl ether b-cyclodextrin (Figure 24-1). This compound is structurally identical to allopregnanolone, a breakdown product of progesterone.

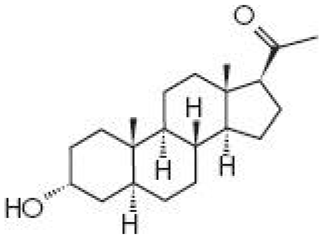

FIGURE 24-1. Chemical structure of brexanolone.

Dosage Forms and Administration

Brexanolone is available at an allopregnanolone concentration of 100 mg/20 mL. Zulresso (brexanolone) injection for intravenous use is available in single-use vials at a concentration of 100 mg/20 mL (5 mg/mL).

Brexanolone requires further dilution prior to administration. Detailed instructions are provided in the product labeling (Sage Therapeutics 2019).

Pharmacological Profile

Brexanolone is a PAM of the $GABA_AR$, with allopregnanolone being the endogenous neuroactive steroid.

Brexanolone is more than 99% protein bound. It is administered intravenously over 60 hours with a titration schedule.

Pharmacokinetics

Brexanolone is available only via the intravenous route because of the poor bioavailability of allopregnanolone. However, depression trials have been conducted with zuranolone (formerly SAGE-217), an oral synthetic neurosteroid and PAM of $GABA_A$ receptors. Zuranolone has been tested in populations with major depressive disorder (MDD) and PPD with success (Deligiannidis *et al.* 2021; Gunduz-Bruce *et al.* 2019), and in August 2023, it became the first oral medication to receive FDA approval for the treatment of PPD in adults (U.S. Food and Drug Administration 2023).

When brexanolone is given intravenously, it exhibits dose-proportional pharmacokinetics over a dosage range of 30-270 mg/kg/hour. Brexanolone is metabolized by non-cytochrome P450 pathways into three inactive metabolites through keto-reduction, glucuronidation, and sulfation, with a terminal half-life of 9 hours. These metabolites are eliminated in feces (47%) and urine (42%), with less than 1% eliminated in the urine as unchanged drug. The total plasma clearance of brexanolone is approximately 1 L/hour/kg. Brexanolone should be avoided in end-stage renal disease with an estimated glomerular filtration rate of less than 15 mL/minute/1.73 m^2 because of the potential accumulation of the solubilizing agent betadex sulfobutyl ether sodium (Sage Therapeutics 2019).

Mechanism of Action

Brexanolone is a neuroactive steroid that acts as an antidepressant for women with PPD. Although the etiology of PPD is not fully understood, allopregnanolone concentrations dramatically decline after childbirth, and GABA system dysfunction is thought to play a critical role in PPD. Brexanolone is a PAM of the $GABA_A$Rs. Of note, PAMs of $GABA_A$Rs, such as allopregnanolone, are pharmacologically distinct from benzodiazepines. These neurosteroids bind both synaptic and extrasynaptic receptors, with allopregnanolone being one of the most potent modulators (Meltzer-Brody and Kane 2020). A recent study found that brexanolone infusion reduced levels of the inflammatory markers tumor necrosis factor-a and interleukin-6 and inhibited their response to the inflammatory immune activators lipopolysaccharide and imiquimod, and these effects were correlated with Ham-D score improvement (Balan *et al.* 2023). Thus, brexanolone may achieve its remarkable and sustained therapeutic effects by inhibiting these pathways and/or by changing the sensitivity of immune cells to subsequent stimulation by inflammatory activators.

Indications and Efficacy

In 2019, brexanolone was approved by the FDA for treating PPD in adults. Brexanolone went through one Phase II and two Phase III trials that were multicenter, prospective, double-blind, and placebo controlled for a total of 267 subjects ages 18-45 years (Kanes *et al.* 2017b; Meltzer-Brody *et al.* 2018). The primary efficacy endpoint in all studies was a change in Ham-D score from baseline to the infusion end (hour 60), with a secondary endpoint being Ham-D score at day 30. Brexanolone produced a statistically significant improvement in depressive symptoms when compared with placebo. One criticism of these studies of brexanolone was their limited follow-up, to 30 days after infusion. A subsequent clinical study of patients treated after FDA approval of the drug followed 11 patients to 90 days after treatment and showed continued efficacy, with Ham-D scores lower than at hour 60 (Patterson *et al.* 2022).

Investigative Applications for Neurosteroids

Brexanolone for the treatment of PPD has been studied in adolescents ages 15-17 years, with findings similar to those in the adult trials. Brexanolone was generally well tolerated in this population with Ham-D response being achieved by 75% of participants at the end of infusion (hour 60) and by 89.5% of participants at the end of the trial (day 30) (Riesenberg *et al.* 2022). SAGE-547 (brexanolone) has also been studied in populations with super-refractory status epilepticus and essential tremor (Ellenbogen *et al.* 2016; Rosenthal *et al.* 2017). Allopregnanolone and related neuroactive steroids such as pregnenolone and ganaxolone have been investigated in a number of other psychiatric and medical conditions including major neurocognitive disorders, substance use disorders, stress disorders, and seizure disorders (Besheer *et al.* 2010; Lattanzi *et al.* 2021; Morrow *et al.* 2020; Rasmusson *et al.* 2017; Tomaselli and Vallee 2019).

Zuranolone (SAGE-217; Sage Therapeutics) is a neuroactive steroid being investigated as an oral treatment for MDD, PPD, insomnia, bipolar depression, and Parkinson's disease (Althaus *et al.* 2020; Bullock *et al.* 2021, 2022; Deligiannidis *et al.* 2021; Gunduz-Bruce *et al.* 2019). It is a GABA$_A$R PAM that has a pharmacokinetic profile and mechanism of action that are suitable for oral once-daily dosing (Deligiannidis *et al.* 2021; Hoffmann *et al.* 2020). Zuranolone was granted a breakthrough therapy designation by the FDA in October 2021 (Biogen 2021a). Zuranolone's new drug application has been accepted by the FDA, and a priority decision review was conducted in August 2023 (Biogen 2023). On August 4, 2023, zuranolone became the first oral medication to receive FDA approval for the treatment of PPD in adults (U.S. Food and Drug Administration 2023).

Major Depressive Disorder Trials

In a double-blind Phase II trial of zuranolone in patients with moderate to severe major depressive disorder, 89 patients were enrolled to receive either 30 mg of SAGE-217 or placebo once daily for 14 days. The primary endpoint was a change in Ham-D score from baseline to day 15. Forty-five patients were randomly assigned to the SAGE-217 group and 44 to the placebo group. The least-squares mean reduction in Ham-D score at day 15 for the SAGE-217 group was 17.4 points (SE 1.3), and the reduction for the placebo group was 10.3 points (SE 1.3; 95% CI, [?] 10.2 to [?] 3.9; *P* < 0.001) (Gunduz-Bruce *et al.* 2019). A number of Phase III trials with zuranolone are under way for treatment of MDD, with results pending, including successful trials when zuranolone is co-initiated with other antidepressant therapy (Biogen 2021b). However, recent data reported from the Phase III MOUNTAIN trial of zuranolone treatment in adults with MDD indicated that the trial did not meet its primary endpoints (Clayton *et al.* 2023).

Postpartum Depression Trials

A Phase III double-blind, randomized, placebo-controlled trial of zuranolone was conducted among patients with severe PPD (Ham-D score [?] 26) from 2017 to 2018. As in the brexanolone trials, patients were women ages 18-45 years with a major depressive episode occurring in the third trimester or within the first 4 weeks postpartum who were [?] 6 months postpartum at the time of enrollment. The trial enrolled 153 subjects, 77 of whom were randomly assigned to receive 30 mg of zuranolone daily for 14 days and 76 of whom were in the placebo group. The primary endpoint was a change in Ham-D score from baseline to day 15. The primary endpoint was achieved, with the zuranolone group reporting significantly lower Ham-D scores at day 15 compared with the placebo group (least-squares mean, [?] 17.8 points vs. [?] 13.6 points; 95% CI [?] 6.9 to [?] 1.5; *P* = 0.003) (Deligiannidis *et al.* 2021). Subjects receiving zuranolone had a sustained greater reduction in Ham-D scores in comparison with the placebo group beginning at day 3 and continuing through the last follow-up at day 45. Phase III trials with zuranolone are ongoing, and the current data reflect an exciting new oral treatment for postpartum depression.

Other Trials

Zuranolone has also been investigated for the treatment of insomnia, Parkinson's disease, and bipolar depression. Data from clinical trials are not yet available for bipolar depression, but promising results have been reported from the insomnia and Parkinson's trials. A Phase I double-blind, placebo-controlled trial (ClinicalTrials.gov number NCT03284931) for the use of zuranolone to treat insomnia enrolled 45 patients who were given varying doses of zuranolone (30 mg vs. 45 mg) or placebo during a single sleep cycle. Patients who received zuranolone reported significantly greater improvements in sleep efficiency when compared with the placebo group (30 mg, 84.6%; 45 mg, 87.6%; placebo, 72.9%; $P < 0.001$ for both dosages) (Bullock *et al.* 2022). Results from a Phase II open-label trial of zuranolone for Parkinson's disease have reported promising data for the use of zuranolone in reducing parkinsonian tremor (Bullock *et al.* 2021).

Side Effects and Toxicology

Brexanolone

Brexanolone has a black box warning regarding excessive sedation and sudden loss of consciousness. During clinical studies, 5% of brexanolone-treated subjects experienced excessive sedation that necessitated dosage interruption or reductions, and 4% experienced loss of consciousness. To address these rare but serious side effects, the FDA mandated several safety parameters, including a Risk Evaluation and Mitigation Strategy (REMS), which requires continuous pulse oximetry and every-2-hour sedation scale monitoring; in addition, patients must be accompanied by an adult during interactions with their infant for the duration of the infusion (U.S. Food and Drug Administration Center for Drug Evaluation and Research 2016). The Zulresso REMS program requires that all health care settings, pharmacies, physicians, and patients enroll in the restricted program. If a patient becomes sedated, the infusion should be stopped until the patient returns to the baseline alertness level. At that time, the infusion could be resumed at a lower, better-tolerated dose. If the patient becomes hypoxic at any time during the infusion, it should be stopped and not restarted.

Information about the REMS program for brexanolone is available from the FDA website (www.fda.gov), which hosts a database of all REMS programs and their unique requirements. A Patient Medication Guide is also provided as part of the brexanolone product labeling (Sage Therapeutics 2019).

Additional common adverse reactions with brexanolone (incidence [?] 5% and at least twice the rate of placebo) include mild sedation or somnolence (21%), presyncope, dizziness, or vertigo (13%), dry mouth (11%), and flushing or hot flashes (5%) (Sage Therapeutics 2019).

Pregnancy

No human data on use of brexanolone in pregnancy are available. Previous studies in animal models at twice the maximum recommended human dosage suggested fetal harm. Subjects in the brexanolone clinical trial had negative pregnancy tests and used approved birth control for 30 days after infusion.

Lactation

According to data from 12 women infused in the clinical trials, brexanolone is transferred to and present in breast milk (Hoffmann *et al.* 2019). The maximum relative infant dosage during infusion was 1%-2% of the maternal weight-adjusted dosage, and concentrations of brexanolone were < 10 ng/mL 36 hours after the end of infusion. Additionally, brexanolone has low oral bioavailability in adults (< 5%), so infant exposure is thought to be low as well.

Zuranolone and Other Neurosteroids

Reported side effects of zuranolone and related neurosteroids are similar to those of the brexanolone injection, but no reports of loss of consciousness have occurred to date. Common reported adverse events across zuranolone clinical trials include headache, dizziness, nausea, somnolence, dry mouth, and sedation (Bullock *et al.* 2021, 2022; Deligiannidis *et al.* 2021; Gunduz-Bruce *et al.* 2019).

Drug-Drug Interactions

There may be an increased risk for excessive sedation and loss of consciousness when brexanolone is used with other CNS depressants. Clinicians should be particularly careful with coadministration of GABAergic medications, including opioids and benzodiazepines, because these agents could potentiate the sedative effects. Caution should be taken with patients who have an active alcohol use disorder. Additionally, in placebo-controlled studies, patients with concomitant brexanolone and antidepressant use reported more sedation than did patients receiving placebo (Kanes *et al.* 2017b; Meltzer-Brody *et al.* 2018; Sage Therapeutics 2019).

Conclusion

Brexanolone and zuranolone are currently the only FDA-approved treatments for PPD. Brexanolone is the synthetic form of allopregnanolone, a breakdown product of progesterone, levels of which plummet at the time of delivery. Zuranolone has a pharmacokinetic profile and mechanism of action that are suitable for oral once-daily dosing. These neuroactive steroids are PAMs of the GABA system, and dysfunction in this system's signaling has been implicated in PPD. PPD is the most common complication of childbirth, with estimates of around 15%. Unfortunately, it has been very difficult to treat to remission, and many women suffer for prolonged periods of time, with negative consequences that extend to their families. Brexanolone and zuranolone are rapid-acting, with novel mechanisms of action and delivery systems, which makes them different from typical antidepressant treatments. Long-term benefits remain largely unknown, although one study has shown continued efficacy for brexanolone at 90 days after infusion (Patterson *et al.* 2022).

Antipsychotics

CHAPTER 25

Classic Antipsychotic Medications

Henry A. Nasrallah, M.D.
Rajiv Tandon, M.D.

History and Discovery

Before the introduction of classic antipsychotic medications in the 1950s, treatment for psychotic disorders consisted primarily of institutional confinement and supportive care, with minimal control of psychotic symptoms. The discovery of chlorpromazine, the first of the "classic" antipsychotics, was serendipitous and owes much to the observations of a French surgeon, Henri Laborit, who noted that chlorpromazine, when used as an adjunct to anesthesia, calmed patients significantly after surgery. Laborit recommended its use to two French psychiatrists, Jean Delay and Pierre Deniker, who used it successfully for psychotic patients. Heinz Lehmann was the first to use chlorpromazine in North America (in Montreal, Canada). In the early 1960s, the first large-scale placebo-controlled trials were conducted within the U.S. Veterans Administration system.

After the successes of chlorpromazine, numerous other phenothiazines were synthesized by modification of the side chains on the phenothiazine rings. Subsequently, several nonphenothiazine antipsychotics, such as haloperidol, were introduced. The last of these drugs approved by the FDA was molindone, introduced in 1975. Of 51 classic antipsychotic drugs (representing eight different chemical classes) available in the world, 9 are currently available in the United States.

The ability of chlorpromazine and other conventional antipsychotics to suppress psychotic symptoms (delusions, hallucinations, and disorganization) had a profound impact on chronically hospitalized psychiatric populations worldwide. Many psychiatric patients were discharged from state hospitals to the community. This period of deinstitutionalization led to a decrease in the number of patients in state and county mental hospitals in the United States from 559,000 in 1955 to 338,000 in 1970 to 107,000 in 1988, an 80% decrease over 30 years. Initially, this decrease led to enthusiasm about the possibility that individuals with schizophrenia and other psychoses would be able to function well in the community. However, it soon became apparent that improvement with antipsychotic treatment was incomplete. In addition, poor treatment adherence--with subsequent relapses--led to frequent rehospitalization (i.e., the "revolving door" phenomenon).

As psychiatrists began using chlorpromazine, they observed that treated patients often manifested signs and symptoms of parkinsonism. Along with other side effects such as dystonia and akathisia, these symptoms are collectively called extrapyramidal side effects (EPS). Because of the high prevalence of these movement disorders among patients receiving antipsychotic treatment, many psychiatrists believed EPS to be an unavoidable accompaniment of antipsychotic action; in fact, the onset of some EPS was considered to indicate the minimal effective antipsychotic dosage (i.e., the "neuroleptic threshold"). The first report of persistent orobuccal movements (later called tardive dyskinesia) came from France in 1959. The pervasiveness of debilitating short-term and long-term motor side effects associated with classic antipsychotic drugs led to a search for agents that would be at least as efficacious but without the risk of EPS.

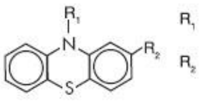
Clozapine, a dibenzodiazepine synthesized in 1959, was the first antipsychotic drug without EPS (i.e., an atypical antipsychotic). It was initially marketed in Europe in 1972 but was withdrawn in some countries in 1975 after several reports of fatalities secondary to agranulocytosis. Clozapine was not introduced in the United States until 1989, after convincing studies demonstrated its efficacy in antipsychotic-refractory schizophrenia. Other atypical agents (also called second-generation antipsychotics [SGAs]) have been launched in the past three decades and are reported to be associated with lower levels of EPS and a broader spectrum of efficacy; of the more than 20 SGAs currently being marketed, 13 are available in the United States (see Chapters 26-35 in this textbook). Since the introduction of these newer agents, use of the classic antipsychotics (also called traditional, conventional, or first-generation antipsychotics [FGAs]) has declined, especially in the United States; FGAs account for approximately 5% of all antipsychotic prescriptions in the country. Results of several government-sponsored effectiveness studies--for example, the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE)--have challenged the prevailing worldview of the greater effectiveness of SGAs over FGAs and have reinvigorated interest in the utility and clinical applicability of classic antipsychotics.

Structure-Activity Relations

Phenothiazines

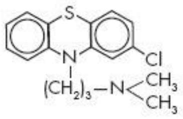
Members of the phenothiazine class of classic antipsychotics share the same basic phenothiazine ring but differ in substitutions at both their R1 and R2 positions (Figure 25-1). Based on the side chain attached to the nitrogen atom in the middle ring (R1), the phenothiazines are further subdivided into three subtypes: aliphatic, piperidine, and piperazine phenothiazines.

Basic phenothiazine ring

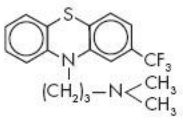


A. Phenothiazines

1. Aliphatic

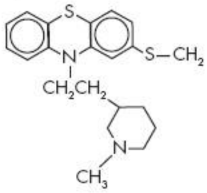


Chlorpromazine

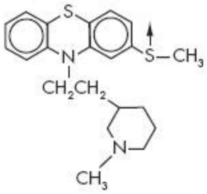


Triflupromazine

2. Piperidine

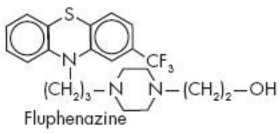


Thioridazine

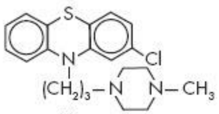


Mesoridazine*

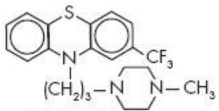
3. Piperazine



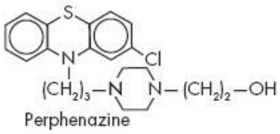
Fluphenazine



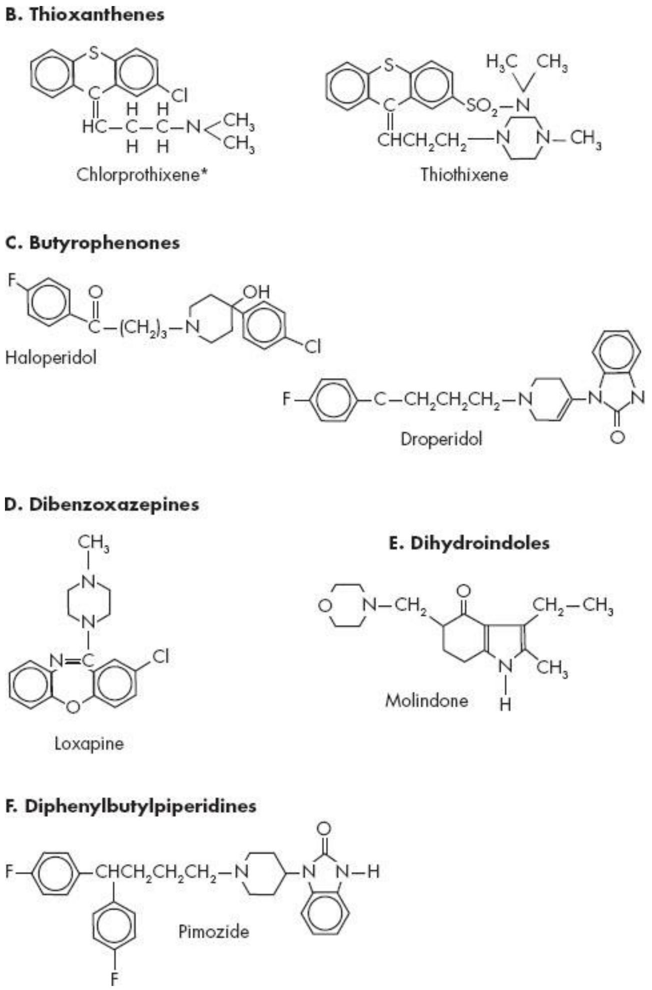
Prochlorperazine



Trifluoperazine



Perphenazine



B. Thioxanthenes

C. Butyrophenones

D. Dibenzoxazepines

E. Dihydroindoles

F. Diphenylbutylpiperidines

FIGURE 25-1. Chemical structures of various classic antipsychotics.

*No longer available in the United States.

Aliphatic Phenothiazines

The aliphatic phenothiazines share a dimethylamide substitution at their tenth carbon. Chlorpromazine (Thorazine or Largactil) is the prototypical member of this class and remains the aliphatic phenothiazine most widely used throughout the world. With a chlorine atom attached to its second carbon, chlorpromazine is heavily sedating because of its high level of anticholinergic, anti-a-adrenergic, and antihistaminergic actions.

Piperidine Phenothiazines

Piperidine phenothiazines--for example, thioridazine (Mellaril) and its metabolite, mesoridazine (Serentil)--are named for the presence of a piperidine ring at their tenth carbon. Although members of this group have similar efficacy and side effects compared with aliphatic phenothiazines, they are notable for having a less potent effect on nigrostriatal dopamine$_2$ (D_2) receptors and a higher level of anticholinergic activity; consequently, they are associated with a lower frequency of EPS. The use of these agents has been virtually extinguished by a black box warning about significant QTc prolongation that was added to their product label in 2000.

Piperazine Phenothiazines

With a substitution of a piperazine group at the tenth carbon of a phenothiazine, the piperazines have much greater D_2 receptor blockade and a lower affinity for muscarinic, a-adrenergic, and histaminergic receptors. Some of the most potent conventional antipsychotics available in the United States, including fluphenazine (Prolixin), perphenazine (Trilafon), and trifluoperazine (Stelazine), belong to this class. The well-known antiemetic prochlorperazine (Compazine) is also part of this class; although approved for the treatment of psychosis, it is rarely used as an antipsychotic.

Thioxanthenes

Structurally and pharmacologically similar to the phenothiazines, the thioxanthenes also differ widely in their pharmacological profiles based on similar side chain substitutions (see Figure 25-1). For instance, chlorprothixene shares the same dimethylamide and chloride substitution as chlorpromazine, with which it also shares its pharmacological profile. Thiothixene (Navane) has both a piperazine side chain and a strongly electrophilic substitution $[SO_2N(CH_3)CH_3]$, thus sharing the pharmacological profile of the piperazines.

Butyrophenones

The butyrophenone class has a piperidine ring with a three-carbon chain ending in a carbonyl-substituted p-fluorobenzene ring. Haloperidol, arguably the best-known classic antipsychotic, is the most widely used agent in this class. Haloperidol and other members of this class are strong dopamine receptor antagonists and show little antimuscarinic, antihistaminergic, and antiadrenergic activity.

Dibenzoxazepines

Loxapine, the only FDA-approved agent in the dibenzoxazepine class, is composed of a tricyclic ring structure with a seven-member central ring. It has a piperazine side

chain and chlorine at position R2 (see Figure 25-1). It exhibits an intermediate level of D_2 blockade, as well as some serotonin$_2$ (5-HT_2) antagonism. Its side-effect profile is characterized by intermediate sedation and autonomic effects. Loxapine has the distinction of being the most "atypical" of the classic antipsychotics because it is structurally similar to the dibenzodiazepine clozapine. Another notable feature of loxapine is that one of its metabolites, amoxapine, is marketed as an antidepressant.

Dihydroindoles

Molindone is the only member of the dihydroindoles available in the United States. Sharing a similar structure with the indolamines (see Figure 25-1), such as serotonin, molindone has the distinction of being the only classic antipsychotic not associated with any weight gain or a lowering of the seizure threshold.

Diphenylbutylpiperidines

Pimozide, the only agent in the diphenylbutylpiperidine class available in the United States, is approved only for the treatment of Tourette syndrome and has the distinction of possessing the highest selectivity and potency for dopamine D_2 receptors among the conventional antipsychotics. It significantly prolongs the QTc interval, and this has limited its use. Derived from benperidol, pimozide shares many characteristics of the butyrophenones (see Figure 25-1).

Benzamides and Iminodibenzyl Agents

Sulpiride, the prototypical substituted benzamide, is a relatively selective dopamine D_2 antagonist and lacks significant activity on cholinergic, histaminergic, or noradrenergic receptors. Because of this relative selectivity and a lower propensity to cause EPS, sulpiride is one of the more common classic antipsychotics used in Europe. No classic antipsychotic agent from either the benzamide or the iminodibenzyl class is available in the United States.

Pharmacological Profile

The classic conventional antipsychotic drugs have a multitude of effects on various physiological variables through their actions on different neurotransmitter systems. The antipsychotic effects of these agents are believed to occur primarily through antagonism of D_2-type dopaminergic receptors. Therapeutic and adverse effects of D_2 antagonism have been conceptualized in the context of the major dopaminergic tracts present in the brain, which include the mesocortical, mesolimbic (A10), tuberoinfundibular (A12), and nigrostriatal (A8 and A9) tracts.

The effect of D_2 receptor blockade on the mesolimbic dopaminergic systems is believed to represent the putative mechanism of action of conventional antipsychotics, but D_2 blockade in other tracts is believed to result in a number of adverse cognitive and behavioral side effects. Such side effects are common in both animals and human subjects. D_2 receptor antagonism in the mesocortical dopaminergic pathway leads to a blunting of cognition (bradyphrenia) and avolition-apathy (sometimes called the neuroleptic-induced deficit syndrome), which can be difficult to differentiate from the primary negative symptoms of schizophrenic illness itself.

Blockade of the tuberoinfundibular tract projecting to the hypothalamus and pituitary gland results in multiple neuroendocrine side effects processed through the pituitary gland. Although dopamine is involved in increasing the release of most pituitary hormones, it is actually responsible for the tonic inhibition of prolactin release. With significant dopaminergic blockade of the tuberoinfundibular tract, prolactin release is no longer prevented, and the release of other pituitary hormones is no longer increased. High levels of prolactin combined with low levels of follicle-stimulating hormone and luteinizing hormone often result in amenorrhea, galactorrhea, gynecomastia, decreased bone density, impaired libido, and erectile dysfunction.

High levels (exceeding 78%) of D_2 dopaminergic blockade within the nigrostriatal system, which projects to the basal ganglia and caudate, produce some of the most undesirable side effects of conventional antipsychotics. Movement disorders or EPS such as akathisia, rigidity, and hypokinesia were once believed to be necessary "evidence" of a therapeutic antipsychotic dosage. However, the advent of the new-generation antipsychotics that are associated with minimal EPS conclusively refuted this misconception. At higher levels of D_2 blockade, one may also observe dystonia, catalepsy, and a rigid, immobile catatonic state.

Classic antipsychotic agents have varying degrees of activity at serotonergic, cholinergic, noradrenergic, histaminergic, and other nondopaminergic receptors. Although it is unclear whether any of these activities contribute to or interfere with their effectiveness in the treatment of psychotic symptoms, they clearly result in a variety of adverse effects. Because of differences in the pharmacological activity of different classic antipsychotic agents at these receptors, there are predictable differences in their side-effect profiles.

Pharmacokinetics

Generally, the pharmacokinetic profiles of the conventional antipsychotics remain poorly understood. Even for some of the more extensively studied agents, many hundreds of potential metabolites remain undiscovered, and the physiological activity of several metabolites has yet to be adequately defined. Nonetheless, certain general statements can be made about the classic antipsychotics as a group.

Administration and Absorption

Many conventional antipsychotics were available in both oral and intramuscular formulations. Currently there are three antipsychotics available for intramuscular use: chlorpromazine, fluphenazine, and haloperidol. Although common in the past, intravenous usage of parenteral formulations of antipsychotics is not FDA approved. Peak plasma levels with oral preparations are generally reached in 1-4 hours, with these levels being reached slightly more rapidly with liquid concentrates. Oral preparations are extensively metabolized in the liver during their first pass through portal circulation by undergoing a range of transformations, including glucuronidation, oxidation, reduction, and methylation. Steady-state levels are reached in a period of four to five times the half-life of the drug in question.

Intramuscular administration produces faster, more predictable absorption, resulting in peak plasma levels in 30-60 minutes and clinical efficacy as early as 15 minutes.

With intramuscular or intravenous administration, plasma levels may be as much as four times the levels of the oral route because of circumvention of the hepatic first-pass metabolism.

Although 10 classic antipsychotics are available in a long-acting (depot) formulation around the world, haloperidol and fluphenazine are the only classic antipsychotics currently available in such a formulation in the United States. The currently available decanoate forms of both haloperidol and fluphenazine are administered through injection into a major muscle, and the drug is slowly released to the bloodstream over time. As the esterified version of the drug diffuses into other tissues, the ester chain is hydrolyzed, resulting in the smooth release of the drug in question. Fluphenazine decanoate can be given every 2-3 weeks on the basis of its half-life of 7-10 days, whereas haloperidol decanoate may be given every 4 weeks because of its longer half-life. The bioavailability of intramuscular relative to oral administration is two times greater.

Distribution

Most conventional antipsychotics are highly protein bound (85%-90%). This feature is important when other highly protein-bound medications are used concomitantly because of the risk of increasing levels of free or unbound drugs into the toxic range. The antipsychotic drugs are highly lipophilic, which allows unbound portions of the drug to readily cross the blood-brain barrier, with concentrations two times higher in the brain than in the peripheral circulation. The drugs also readily cross the placenta to the fetus in pregnancy.

Metabolism

The conventional antipsychotics are metabolized in the liver by hydroxylation and demethylation to forms that are more soluble and readily excreted by the kidneys and in the feces. Many of these compounds undergo further glucuronidation and remain active as dopamine receptor antagonists. Because of the many active metabolites of the antipsychotic agents, it has not been possible to obtain meaningful correlations between plasma levels and clinical response. Variables such as age, genetic variability between individuals, and coadministration of other drugs cause plasma levels to vary 10-to 20-fold between individuals. The majority of conventional antipsychotics are metabolized by the cytochrome P450 (CYP) enzyme subfamilies. Because CYP2D6 is important for the metabolism of many of these antipsychotics, genetic variation in the rate of 2D6 metabolism should be considered. CYP1A2 and 3A4 subfamily enzymes are also involved in the metabolism of some classic antipsychotics, and this effect may be relevant to understanding drug-drug interactions of those agents.

Excretion

The major routes of excretion of the classic antipsychotics are through urine and feces by way of bile. These drugs are also excreted in sweat, saliva, tears, and breast milk. Elimination half-life varies from 18 to 40 hours for these drugs. Lower dosages of antipsychotics are generally needed for older adults because of decreased renal clearance. Because of the long elimination half-lives of the classic antipsychotics, once-a-day dosing is possible for each of these agents after stabilization.

Mechanism of Action

Dopamine has been at the center of neurobiological theories of psychosis for the past half-century, and even today, all agents approved as antipsychotics share the single common attribute of D_2 receptor antagonism. Amphetamine intoxication served as a drug-induced model of the positive symptoms of schizophrenia. Drugs that blocked dopaminergic receptors, specifically the D_2 receptor, were noted to have greater efficacy and potency as antipsychotics. Because dopaminergic agonists exacerbate psychosis and dopaminergic blockade treats it, dopamine has held central importance in our conceptualization of the neuropharmacology of schizophrenia.

Indications and Efficacy

Schizophrenia and Schizoaffective Disorder

Classic antipsychotics are best known for the acute and maintenance treatment of the psychotic (also known as positive) symptoms of schizophrenia and schizoaffective disorder. The major putative mechanism of action is through D_2 blockade of the mesolimbic tract. In many patients, this blockade results in a measurable decrease in the positive symptoms of schizophrenia, including hallucinations, delusions, and disorganization (Tandon *et al.* 2010, 2013). However, negative and cognitive symptoms of schizophrenia respond less robustly. In fact, they may be worsened by blockade of mesocortical tracts that play roles in cognition and hedonic reinforcement.

The failure to improve the negative symptoms of schizophrenia is one of the major drawbacks of the classic antipsychotics. In fact, the EPS induced by the FGAs can worsen negative and cognitive symptoms by inducing bradykinesia and bradyphrenia. Another major limitation is the lack of improvement of positive symptoms (i.e., refractoriness) in about 25% of patients with schizophrenia and partial response (i.e., treatment resistance) in another 25%.

Substance-Induced Psychosis

As noted previously, conventional agents can reverse the psychosis associated with acute and chronic amphetamine intoxication and that associated with cocaine use. However, the risk of acute dystonia must be considered in these populations, because dopamine receptor downregulation is common, resulting in greater sensitivity to rapid D_2 blockade. Results in treatment of psychosis secondary to drugs acting in nondopaminergic mechanisms (such as hallucinogens) are less satisfactory, although there may be some role for the classic antipsychotics in treating phencyclidine psychosis.

Personality Disorders

Although any personality disorder can be associated with transient psychotic features emerging under stressful conditions, Cluster B disorders are most often associated with this phenomenon. Treatment for transient psychotic episodes has included short-term use of low dosages of a high-potency antipsychotic. Although some symptoms

of personality disorders may be amenable to such pharmacological treatment, long-term conventional antipsychotic treatment is not recommended.

Mood Disorders

The utility of antipsychotic agents in the treatment of mood disorders with psychotic features is well known. However, their utility in the treatment of nonpsychotic depression and bipolar disorder is described as well. Several conventional antipsychotics (such as thioridazine) are FDA approved for the treatment of depression and anxiety without overt psychosis. However, they are no longer used for this purpose because of the availability of other, more effective and better-tolerated agents. The utility of conventional agents as adjuncts to mood stabilizers in the treatment of patients with bipolar and related disorders has been well described, both in the acute management of mania and in the maintenance treatment of bipolar disorder with severe mood disturbance or psychotic features. However, the newer atypical antipsychotics have largely replaced conventional antipsychotics in the management of bipolar disorder.

Tourette Syndrome

The tics present in Tourette syndrome are believed to be due to a hyperdopaminergic state that is amenable to treatment by dopamine receptor antagonists. Pimozide is the only conventional antipsychotic with this indication, which is its only FDA-approved indication.

Huntington's Disease

Although there is no cure for Huntington's disease, the psychosis and choreiform movements associated with this disease may be ameliorated by dopamine receptor antagonism. Several conventional antipsychotics carry FDA indications for treatment of this disease.

Nausea, Emesis, and Hiccups

The lower-potency antipsychotics exert a potent antiemetic effect through histamine_1 (H_1) receptor antagonism. This effect is closely related to their original role in reducing perioperative stress and emesis. Many well-known antiemetics, such as promethazine (Phenergan), are phenothiazines with a short-chain substitution. In addition, chlorpromazine is approved for oral or intramuscular therapy of intractable hiccups.

Side Effects and Toxicology

As noted earlier, side-effect profile--rather than efficacy in treating psychosis--is used to differentiate the conventional antipsychotics (Dold *et al.* 2015). These agents serve as antagonists at four major neurotransmitter receptor systems in the CNS: the dopamine type 2 receptor family (D_2, D_3, and D_4), muscarinic cholinergic receptors (M_1), a-adrenergic receptors (a_1 and a_2), and histamine receptors (H_1) (Table 25-1).

TABLE 25-1. Relative affinities of classic antipsychotics to various neurotransmitter receptors

	Chlorpromazine	Thioridazine	Perphenazine	Trifluoperazine	Fluphenazine	Thiothixene	Haloperidol	Loxapine	Mol
D_1	High	--	High	High	High	Moderate	High	High	Lov
D_2	High	Very high	Very high	Very high	Very high	Very high	Very high	Very high	Ver
D_3	High	Very high	Unknown	Unknown	Very high	Unknown	Very high	Unknown	Unk
D_4	High	Very high	Unknown	High	Very high	Unknown	Very high	Very high	Lov
H_1	High	High	Moderate	Moderate	High	Moderate	Low	High	Ver
M_1	High	High	Low	Low	Low	Low	Low	Moderate	Nor
a_1	Very high	Very high	High	High	High	Moderate	Low	High	Lov
a_2	Moderate	Very high	Moderate	Low	Low	Moderate	Low	Low	Mo
5-HT_1	Low	Low	Low	Low	Low	Low	Low	Low	Lov
5-HT_2	High	High	Moderate	Moderate	Moderate	Moderate	Moderate	Very high	Lov

Note. Receptor families: dopamine (D_1, D_2, D_3, D_4), histamine (H_1), muscarinic cholinergic (M_1), a-adrenergic (a_1, a_2), and serotonergic (5-HT_1, 5-HT_2).

The therapeutic action of the classic antipsychotics in ameliorating the positive symptoms of schizophrenia is believed to be due to D_2 blockade in the mesolimbic dopamine tract. Blockade of D_2 receptors in the mesocortical, nigrostriatal, and tuberoinfundibular systems leads to the tract-related side effects described earlier in this chapter (see section "Pharmacological Profile"). Lower-potency agents have greater antihistaminergic, anticholinergic, and antiadrenergic actions. However, they have fewer D_2-related side effects because of their lower affinity to D_2 receptors and high anticholinergic activity.

Higher-potency agents, such as haloperidol, produce more D_2-related movement disorders and prolactin elevation but otherwise have a cleaner side-effect profile, having fewer anticholinergic, antiadrenergic, and antihistaminergic side effects. Anticholinergic action often leads to dry mouth (xerostomia), blurred vision (mydriasis), constipation, urinary retention, sinus tachycardia, confusion, impaired cognition, paralytic ileus, exacerbation of open-angle glaucoma, and drowsiness. Antagonism of a_1-adrenergic receptors is associated with orthostatic hypotension, QTc prolongation, reflex tachycardia, dizziness, incontinence, and sedation. Antagonism of a_2 receptors can be associated with retrograde ejaculation and priapism. Antagonism of H_1 receptors leads to sedation, drowsiness, and weight gain.

The frequencies of adverse reactions to classic antipsychotic agents are summarized in Table 25-2.

TABLE 25-2. Incidence of adverse reactions to classic antipsychotics at therapeutic dos

	Phenothiazines						Butyrophenone
	Chlorpromazine	**Mesoridazine***	**Thioridazine**	**Fluphenazine**	**Perphenazine**	**Trifluoperazine**	**Haloperidol**

Cognitive Side Effects

CNS side effects of the classic antipsychotics can be subclassified into cognitive and neuromuscular side effects. Cognitive effects include sedation, confusion, disturbed concentration, memory impairment, and delirium (Himelhoch *et al.* 1996). Antihistaminergic and anticholinergic actions lead to sedation and slowed mentation. These effects, which are most pronounced with lower-potency agents (e.g., chlorpromazine), are most severe earlier in treatment, with some tolerance developing over time. Anticholinergic delirium is the most common cause of medication-induced delirium. Because delirium is associated with high rates of morbidity and mortality (> 20% mortality), this potential side effect is important, especially for individuals who are more sensitive to anticholinergic medications, such as older adults. In addition, every antipsychotic--but especially the low-potency agents--can potentially lower the seizure threshold.

Extrapyramidal Side Effects

Neuromuscular CNS side effects are due to antagonism of D_2 receptors in the nigrostriatal dopaminergic pathway. Generally, antipsychotics manifest EPS when dopaminergic blockade exceeds 75% of D_2 receptors. EPS are most common with the high-potency agents such as haloperidol. A greater risk of EPS differentiates the classic from the atypical antipsychotics; in fact, the term *atypical* was originally coined to highlight this ability to produce an antipsychotic effect equivalent to that of the typical high-potency agents with lower potential for EPS.

Acute-Onset EPS

Acute-onset EPS include medication-induced parkinsonism, acute dystonia, and akathisia. *Antipsychotic-induced parkinsonism* occurs in 15% of patients after several weeks of treatment. It is more common in patients older than 40 years, although it can occur at any age. Symptoms are identical to those of Parkinson's disease and include muscle stiffness (lead-pipe rigidity), cogwheel rigidity, shuffling gait, stooped posture, drooling, bradykinesia, resting tremor, masked facies, and akinesia. Slow, restricted movements of the body and face (akinesia) may be mistakenly diagnosed as being due to depression or the negative symptoms of schizophrenia.

It is estimated that up to 10% of patients may experience an acute dystonic episode, which usually occurs within the first few hours or days of treatment. It is more common in youths, in recent cocaine users, and with intramuscular doses of high-potency antipsychotics. Dystonia is an acute, sustained, painful muscular contraction. Potential areas of involvement include the tongue (protrusions, twisting), jaw, neck (spasmodic retrocollis or torticollis), and back (opisthotonos). If the dystonia involves the eyes, it results in a symmetrical or unilateral upward lateral movement called an oculogyric crisis. Laryngeal dystonia can result in sudden death secondary to a patient's inability to breathe. Dystonia can be extremely uncomfortable and frightening for patients and can lead to noncompliance with medication for fear of recurrence. Treatment of dystonia requires rapid diagnosis and intravenous administration of antihistaminergic or anticholinergic agents. Anticholinergic agents are often initiated with high-potency antipsychotics in an effort to avoid this side effect.

Akathisia is a subjective feeling of motor restlessness in which patients feel an irresistible urge to move continuously. It is described as an unpleasant sensation and may result in dysphoria. Akathisia can occur at any time during treatment and is the most prevalent EPS. It often leads to noncompliance with medications and is believed to increase suicide risk in some patients.

Late-Onset EPS

Tardive dyskinesia is characterized by a persistent syndrome of involuntary choreoathetoid movements of the head, limbs, and trunk. It generally takes at least 3 months of exposure to antipsychotics before the disorder develops. Perioral movements involving buccolingual masticatory musculature are the most common early manifestation of tardive dyskinesia. Tardive dyskinesia has an estimated yearly incidence of 5% among adults and as high as 25% in older adults who receive continuous conventional antipsychotic therapy, and it has been a major source of litigation in past psychiatric practice. The risk of developing tardive dyskinesia is reported to increase with age and to be higher in certain ethnic groups; female gender, presence of mood disorders, and early onset of EPS have also been associated with increased risk of tardive dyskinesia.

Tardive dyskinesia may be masked by continuing dopamine blockade and has a variable course following development. Over time, spontaneous resolution or improvement has been described in some patients. There is no single effective treatment, although treatment with clozapine has been reported to improve symptoms. Cases of tardive dyskinesia have been described with every antipsychotic, although classic antipsychotics are associated with a much greater risk of tardive dyskinesia than second-generation or atypical agents (Correll *et al.* 2004). Other tardive syndromes include tardive dystonia, tardive akathisia, and tardive pain.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is a poorly understood syndrome that usually appears within hours or days of initiation of antipsychotic treatment. This syndrome is characterized by muscular rigidity, hyperpyrexia, autonomic instability

(hypotension or hypertension, tachycardia, diaphoresis, pallor), and altered consciousness. NMS has an estimated incidence of 0.02%-2% and carries a mortality rate of 20%-30%. Death most often occurs secondary to dysrhythmias, renal failure secondary to rhabdomyolysis, aspiration pneumonia, or respiratory failure. Laboratory findings include elevated creatine phosphokinase, elevated white blood cell (WBC) count, elevated liver enzymes, myoglobinemia, and myoglobinuria. The syndrome can last up to 14 days.

Treatment requires immediate discontinuation of the offending antipsychotic and supportive care with aggressive intravenous hydration. In the past, mild cases of NMS were treated with intravenous bromocriptine, and more severe cases were treated with intravenous dantrolene. However, randomized controlled clinical trials of NMS treatment have never been performed because of its infrequent occurrence.

Cardiac Effects

a-Adrenergic antagonism is associated with orthostatic hypotension with reflex tachycardia, with tolerance possibly developing later in the treatment course. Orthostasis is important because of an increase in falls and related injuries.

Recent studies involving several antipsychotics have drawn attention to the risk of cardiac dysrhythmias, which is especially prominent with use of lower-potency conventional antipsychotics. High dosage, rapid titration, intramuscular administration, and especially intravenous administration may be associated with a lengthening of the QTc interval, with a resulting risk of serious dysrhythmias such as torsades de pointes and ventricular fibrillation. Studies with thioridazine have raised concerns about piperidine antipsychotics, leading to a decrease in the use of this class. In reality, torsades de pointes is rarely encountered during treatment with conventional antipsychotics, although some have speculated that a syndrome of unexplained sudden death described with all conventional antipsychotics may be related to sudden dysrhythmias.

Gastrointestinal Side Effects

The anticholinergic actions of conventional agents include dry mouth, nausea, vomiting, and constipation that can progress to paralytic ileus. Antihistaminergic action is associated with medication-related weight gain.

Cholestatic jaundice is a hypersensitivity reaction described with the aliphatic phenothiazines, especially chlorpromazine (incidence of 0.1%). This reaction typically manifests during the first 1-2 months of treatment and presents with nausea, malaise, fever, pruritus, abdominal pain, and jaundice, with resulting elevations in levels of bilirubin and alkaline phosphatase. This condition rarely lasts > 2 weeks after discontinuation.

Weight Gain, Diabetes Mellitus, and Dyslipidemia

With the introduction of atypical antipsychotics, several of which cause significant weight gain, there is renewed awareness of the metabolic side effects associated with antipsychotic therapy such as obesity, elevated cholesterol and triglyceride levels, and an increased risk of diabetes mellitus. These metabolic changes increase the risk of ischemic heart disease and contribute to the increased mortality observed in

schizophrenia. Antihistaminergic action is associated with medication-related weight gain, which greatly increases the patient's risk of developing diabetes. Diabetes is currently described as a worldwide epidemic. Serotonin 5-HT_{2C} receptor blockade also significantly contributes to weight gain (Tandon and Halbreich 2003). There are significant differences between classic antipsychotics with reference to their propensity to cause these metabolic adverse effects. Molindone is the least likely to cause weight gain, whereas thioridazine and chlorpromazine are among the most likely to do so. In general, high-potency agents cause less weight gain than do low-potency agents.

Genitourinary Side Effects

Renal effects secondary to blockade of M_1 receptors include urinary hesitancy or retention, which can lead to a comparable increase in urinary tract infections in both sexes. As mentioned previously, antagonism of tuberoinfundibular dopaminergic tracts increases prolactin secretion. Clinical manifestations of hyperprolactinemia include gynecomastia, galactorrhea, diminished libido, erectile dysfunction, amenorrhea, decreased bone density, menstrual irregularities, infertility, delayed ovulation, and possibly increased risk of breast cancer. Other sexual side effects, such as erectile disorder, retrograde ejaculation (due to blockade of a_2-adrenergic receptors), anorgasmia, and occasionally priapism, can also occur with conventional antipsychotics.

Hematological Side Effects

Hematological effects of conventional antipsychotics include transient leukopenia (WBC count < 3,500/mm^3), which is common but not usually problematic, and agranulocytosis (WBC count < 500/mm^3), a life-threatening problem. Agranulocytosis occurs most often during the first 3 months of treatment, with an incidence of 1 in 500,000. Aliphatic and piperidine phenothiazines are the most common causal agents among the conventional antipsychotics. Rarely, thrombocytopenic or nonthrombocytopenic purpura, hemolytic anemia, and pancytopenia may occur.

Ocular Side Effects

In addition to direct anticholinergic ocular effects such as blurred vision (mydriasis and cycloplegia) and exacerbation of open-angle glaucoma, direct optic toxicity has been described. The conventional antipsychotics are associated with several kinds of optical pathology involving the lens, cornea, and retina. Lenticular opacities have been reported with some phenothiazines, including perphenazine, chlorpromazine, and thioridazine. An irreversible increase in retinal pigmentation has been described with thioridazine when high dosages (> 800 mg/day) are used. This retinal pigmentation, which can progress even after drug discontinuation, can lead to reduced visual acuity and even blindness. Early symptoms include poor night vision and secondary nocturnal confusion.

Dermatological Side Effects

Cutaneous side effects of the conventional antipsychotics involve hypersensitivity rashes--most commonly maculopapular erythematous rashes of the trunk, face, neck, and extremities--and photosensitivity reactions that can lead to severe sunburn. Care must be taken with injectable versions of many antipsychotics because of the risk of direct dermatological toxicity if the skin or subcutaneous layers are exposed. Prolonged use of chlorpromazine can lead to blue-gray discoloration in body areas exposed to sunlight.

Neurotoxicity

Over the past 20 years, 32 studies published in neuroscience journals have reported on the neurotoxic effects of haloperidol and several other first-generation agents. These neurotoxic effects are mediated by 15 different molecular mechanisms (reviewed in Nasrallah and Chen 2017). A meta-analysis of 18 neuroimaging studies comparing FGAs and SGAs confirmed the finding of progressive atrophy of brain volume in individuals maintained on first-generation but not second-generation agents (Vita *et al.* 2015). In our opinion, those studies should prompt clinicians to avoid use of the FGAs and instead to use one of the SGAs, which as a class have been demonstrated to have at least 24 different neuroprotective effects in the brains of patients receiving them (reviewed by Chen and Nasrallah 2019).

Drug-Drug Interactions

Careful consideration should be given to a patient's existing drug regimen before the initiation of antipsychotic therapy.

Protein Binding

Because conventional antipsychotics are tightly protein bound, care must be taken when these medications are administered with other highly protein-bound medications. Mutual displacement of medications such as phenytoin, digoxin, warfarin, and valproate could lead to a short-term increase in serum levels of these drugs and of the conventional antipsychotic. However, protein binding has not been of serious clinical significance.

CYP Inhibition

As mentioned previously, conventional antipsychotics are primarily hepatically metabolized through the CYP2D6 and 3A4 enzymes. In addition, each inhibits the 2D6 enzyme to some degree. Care must be taken when conventional agents are coadministered with potent CYP2D6 inhibitors such as fluoxetine, paroxetine, cimetidine, erythromycin, and certain class IC antiarrhythmics (e.g., quinidine). Similarly, potent CYP3A4 inhibitors such as nefazodone, fluvoxamine, and ketoconazole should be used with care. Inhibitors of CYP2D6 and 3A4, as well as competitive substrates, should be used carefully with conventional antipsychotics because of their potential to increase plasma levels. CYP1A2, induced by nicotine and inhibited by estrogen, plays a role in metabolizing some antipsychotics.

Conclusion

The classic antipsychotics revolutionized the practice of psychiatry and the treatment of patients with severe mental illness throughout the world. Second-generation

"atypical" antipsychotics have commercially eclipsed these first-generation agents to a large extent, such that more than 90% of patients with schizophrenia and related psychoses in the United States are currently receiving one of the atypical oral agents. In regard to long-acting (depot) agents, second-generation injectable agents are gradually displacing classic antipsychotic injectables such as haloperidol decanoate and fluphenazine decanoate. The landmark National Institute of Mental Health-funded CATIE study, which compared four SGA oral agents (olanzapine, quetiapine, risperidone, and ziprasidone) against one FGA oral agent (perphenazine), showed that there was no difference between the two generations in clinical effectiveness (defined as time to all-cause treatment discontinuation) (Lieberman *et al.* 2005). However, the CATIE study excluded subjects with tardive dyskinesia from random assignment to perphenazine and instead assigned them to one of the atypical agents. This methodological stipulation may have confounded the findings, because the 231 subjects with tardive dyskinesia were later found to have a higher severity of psychopathology and a much greater likelihood of substance use (Nasrallah 2006). Additionally, the subjects' low propensity to develop EPS led to a ceiling effect finding of no EPS differences between perphenazine and the SGAs. Nonetheless, both classic antipsychotics and atypical antipsychotics can cause serious side effects, with neurological adverse events being much more likely with the FGAs and metabolic complications being more common with the SGAs.

Conventional antipsychotics will always be remembered for their critical role as the foundation of antipsychotic pharmacotherapy and as the main impetus for the remarkable neuropharmacological progress in psychiatric neuroscience over the second half of the twentieth century. They retain an important, if limited, role in the antipsychotic armamentarium of the twenty-first century.

CHAPTER 26

Clozapine

Yvonne S. Yang, M.D., Ph.D.
Stephen R. Marder, M.D.

History and Discovery

Clozapine has played a critical role in the history of therapeutics for psychosis. When clozapine was initially developed in the 1960s (following its synthesis in 1958 in Switzerland), there was skepticism as to whether an agent that barely caused catalepsy in rodents could be an effective antipsychotic. According to Hippius (1999), there was limited enthusiasm for this drug because its profile was inconsistent with the "neuroleptic dogma" that extrapyramidal side effects (EPS) were an essential feature of an antipsychotic agent. Nevertheless, Hippius and others challenged this dogma and supported clozapine's development in Germany. As a result, clozapine was eventually marketed in several countries in Europe.

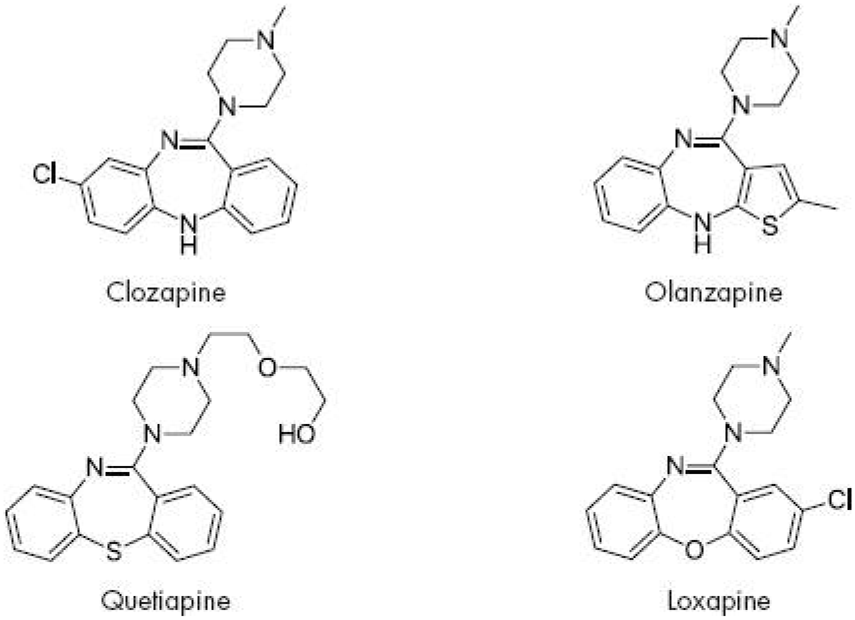
Enthusiasm about clozapine's unique profile evaporated when it was reported that 13 patients in Finland developed agranulocytosis during treatment with clozapine and that 8 of these patients died (Griffith and Saameli 1975). This news led to a near-halt in research on clozapine, and in the United States, clozapine's investigational new drug application came to a halt. However, attempts to switch patients to other antipsychotic agents resulted in substantial deterioration in some individuals (Hippius 1999). Some of these patients were switched back to clozapine and were carefully monitored with regular white blood cell (WBC) counts. Thus, it was found that if clozapine was discontinued, the agranulocytosis reversed and the drug could be readministered safely (Honigfeld *et al.* 1998). Moreover, studies revealed that clozapine was particularly effective for patients who were severely ill and for those who had failed to respond to treatment with conventional antipsychotics. After a series of stops and starts, clozapine was finally demonstrated to have superiority over chlorpromazine for treatment-resistant schizophrenia and was approved by the FDA in 1990 (Crilly 2007; Iqbal *et al.* 2003; Kane *et al.* 1988).

The discovery that clozapine was an effective antipsychotic that caused minimal EPS led to a reassessment of the reigning models of the antipsychotic effect. The exact mechanism of clozapine's antipsychotic action was and remains unknown. However, its greater

efficacy than first-generation antipsychotics (FGAs) led to the development of the second-generation antipsychotics, or SGAs. Attempts to understand clozapine's mechanism of action have raised more questions than answers in our understanding of the physiology and pharmacology of schizophrenia, yet it remains the most effective antipsychotic.

Structure-Activity Relationships

Clozapine, or 3-chloro-6-(4-methylpiperazin-1-yl)-5*H*-benzo[b][1,4]benzodiazepine (National Center for Biotechnology Information 2022a, 2022d), belongs to the group of tricyclic antipsychotics known as the dibenzazepines. This group is characterized by a seven-member dibenzazepine central ring substituted with oxygen, nitrogen, sulfur, or carbon (Iskra and Decker 2012). The antipsychotic dibenzepines include a loxapine-like group of compounds (the dibenzoxazepines) and a clozapine-like group (the dibenzodiazepines). The structures of clozapine and its derivatives olanzapine and quetiapine can be seen in Figure 26-1. Interestingly, the structure of the FGA antipsychotic loxapine is quite similar to that of clozapine (National Center for Biotechnology Information 2022a, 2022b, 2022c), with only two substitutions distinguishing them.



Clozapine

Olanzapine

Quetiapine

Loxapine

FIGURE 26-1. Chemical structures of clozapine, olanzapine, quetiapine, and loxapine. Olanzapine and quetiapine were based on clozapine's chemical structure, and their similarities can be seen clearly here. It is also striking how similar the structure of loxapine, a typical antipsychotic, is to that of clozapine, the prototypical atypical antipsychotic.

Source. Adapted from PubChem Compound Database, National Center for Biotechnology Information (https://pubchem.ncbi.nlm.nih.gov/pccompound).

Clozapine is also known to be a fast-off dopamine$_2$ (D_2) receptor antagonist, with a rapid disassociation time of less than 1 minute for 50% binding of D_2 receptors (Seeman 2014). Tresadern *et al.* (2011) examined more than 1,800 compounds and found that "increased hydrophilicity, increased number of nitrogen atoms, lower MW [molecular weight], fewer rings, less chiral centers, and increased partial positive charge all contribute to a faster dissociation from the D_2 receptor" (p. 27).

Pharmacological Profile

To quote Wenthur and Lindsley (2013), "clozapine is a broad spectrum ligand" because it binds to more receptors than perhaps any molecule in psychopharmacology (Stahl 2013). Clozapine and the other SGAs are often identified through their equal or greater antagonism of the serotonin$_{2A}$ (5-

HT_{2A}) receptor compared with their D_2 receptor antagonism. However, clozapine in fact binds to more than 20 receptors more strongly than in toes to the D_2 receptor and to at least four receptors equally or more strongly than to the 5-HT_{2A} receptor (Stahl 2013; Wenthur and Lindsley 2013). Of all the antipsychotics, quetiapine, whose structure was based on that of clozapine, is most similar in pharmacological profile to clozapine.

Dopamine Receptors

Clozapine is a D_2 antagonist that binds D_2 receptors approximately 50-100 times more weakly than haloperidol and 10 times more weakly than chlorpromazine (Ashby and Wang 1996). At therapeutic concentrations, clozapine occupies only 40%[?]60% of D_2 receptors, in contrast to most FGAs, which occupy more than 80% of D_2 receptors (Wenthur and Lindsley 2013). Clozapine binds less tightly to D_2 receptors than to dopamine itself and may be displaced by endogenous dopamine (Seeman 2014). It also has equivalent occupancy of $dopamine_1$ (D_1) and D_2 receptors at therapeutic dosages (Tauscher *et al.* 2004). In order, clozapine binds most strongly to $dopamine_4$ (D_4) > D_1 > $dopamine_5$ (D_5) > D_2 > $dopamine_3$ (D_3) receptors (Wenthur and Lindsley 2013).

Serotonin Receptors

Clozapine binds to and antagonizes 5-HT_{2A}, $serotonin_{2B}$ (5-HT_{2B}), and $serotonin_{2C}$ (5-HT_{2C}) receptors 15-30 times more strongly than it does D_2 receptors (Stahl 2013; Wenthur and Lindsley 2013). Clozapine also has high affinity for $serotonin_5$ (5-HT_5) receptors and acts as a partial agonist at $serotonin_{1A}$ (5-HT_{1A}) receptors.

Muscarinic Receptors

Clozapine binds strongly to muscarinic acetylcholine receptors $M_{1\text{-}5}$, with varying of partial agonist versus competitive antagonist activity, depending on the cell line studied (Foster *et al.* 2021). Clozapine's high affinity for muscarinic receptors likely causes many of its well-known side effects, such as sedation, constipation, and the dangerous complication of ileus.

Adrenergic Receptors

Clozapine binds strongly to a_1-adrenergic receptors in the CNS, based on PET studies of ^{3}H-prazosin binding displacement in animal models (Ashby and Wang 1996). Clozapine's a_1-adrenergic receptor antagonism likely contributes to its sedative properties and also to some of its cardiac side effects, including orthostatic hypotension and tachycardia.

Histamine Receptors

Clozapine binds very strongly to histamine$_1$ (H_1) receptors. This likely contributes to its associated sedation and increases in patients' appetite and weight, possibly leading to

diabetes and metabolic syndrome. Preliminary research has been done on histamine agonists to counteract the metabolic effects of SGAs; however, no well-powered, placebo-controlled randomized trials have been performed (Poyurovsky *et al.* 2005).

Glutamate Receptors

Although clozapine does not bind directly to glutamate receptors, it has been shown to inhibit the reuptake of glycine at the synapse in rats, resulting in increased glycine at the synapse and thus increased *N*-methyl-D-aspartate (NMDA) receptor signaling (Javitt *et al.* 2005). Moreover, clozapine's main metabolite, *N*-desmethylclozapine (NDMC), or norclozapine, is an M_1 agonist known to increase NMDA receptor activity (Wenthur and Lindsley 2013).

GABA Receptors

It is hypothesized that clozapine may act on the $GABA_B$ receptor, although thus far direct evidence of binding to GABA receptors has not been observed (Nair *et al.* 2020). Animal behavioral models have been of limited use in schizophrenia due to a lack of well-accepted animal models of psychopathology in schizophrenia. The reasons for this are numerous. First, the high level of complexity of both the contributions of genetics to psychosis and of the symptom domains of psychosis means that a model can only represent part of a psychotic disorder. Second, the subjective quality of many psychotic experiences, such as paranoia, hallucinations, and delusions, make these symptoms and experiences difficult to measure in animals. Third, the human brain is many times more complex than even that of a monkey, not to mention that of a rodent, as evidenced by the large number of folds in the human brain and the complete absence of folds in the rodent brain. Finally, terms such as *schizophrenia* and *psychosis* continue to function as umbrella terms for what is likely numerous diseases presenting with overlapping symptoms and syndromes, making differentiation of one illness from another difficult in humans, and far more so in animal models.

That said, a number of animal models--including prepulse inhibition (PPI), latent inhibition (LI) of the conditioned response, and the conditioned avoidance response (CAR)--are being studied from a more reductionist standpoint. PPI is a sensory gating phenomenon thought to relate to the relative difficulty patients with schizophrenia have with separating salient information from non-salient information in the environment. These models are being seen less as complete models of the disease than as models of specific neurophysiological aspects of psychosis that can inform us about particular characteristics of the illness (Wong and Josselyn 2016), and they suggest unique properties of clozapine. For instance, as reviewed by Geyer *et al.* (2001), deficits in PPI induced by NMDA receptor antagonists were most likely to respond to clozapine-like SGAs and not to FGAs.

Pharmacokinetics and Disposition

Clozapine is readily orally absorbed, and tablets and suspension have equivalent bioavailability. However, due to extensive first-pass metabolism, its absolute oral bioavailability is only about 50%. Peak plasma levels are reached approximately 2 hours after oral administration. The elimination half-life at steady state is about 12 hours, and patients usually reach steady-state plasma concentrations within 5-7 days (HLS Therapeutics 2023). The coadministration of highly protein-bound drugs may lead to increased free clozapine levels, although the total (free plus bound) levels may be unchanged. Clozapine's volume of distribution is lower than that of other antipsychotic drugs but is nonetheless large, with a mean of 2.0-5.1 L/kg (range 1.0-10.2 L/kg). Clozapine easily crosses the blood-brain barrier.

As mentioned, clozapine undergoes extensive first-pass metabolism in the liver and gut. Although it is predominantly metabolized by cytochrome P450 (CYP) 1A2, CYP2D6 and CYP3A3/4 also contribute (Buur-Rasmussen and Brosen 1999; Wenthur and Lindsley 2013). Plasma concentrations of clozapine average about 10-80 ng/mL per milligram of drug given per kilogram of patient weight. Thus, a typical daily dosage of 300-400 mg (about 5 mg/kg) is associated with plasma levels ranging from 200 to 400 ng/mL. However, there is considerable variability among individuals treated with clozapine. Several studies have focused on the clinical implications of this variation, and, when taken together, they indicate that patients are more likely to do well when their plasma levels are greater than 350 ng/mL (Bell *et al.* 1998; Kronig *et al.* 1995; Miller 1996; Miller *et al.* 1994; Potkin *et al.* 1994). If patients have not responded after 6 weeks with a plasma level of 250 ng/mL, the clinician should increase the level to approximately 350 ng/mL. High levels, such as 600 ng/mL, are not associated with a greater likelihood of improvement than moderate levels and may be associated with a higher incidence of side effects, including increased seizure risk. Therefore, patients with high levels and side effects may benefit from having the dosage reduced.

When interpreting plasma concentrations of clozapine, clinicians should consider whether the laboratory is reporting just the parent drug or clozapine plus norclozapine. If the latter, levels will be higher. Generally, the clozapine : norclozapine ratio is between 1.5 and 2; if higher than 3, this may indicate that the clozapine level does not reflect a trough level, whereas if the ratio is less than 1.5, this could indicate saturation and low utility of a higher dose (Couchman *et al.* 2010). A lower ratio may also be associated with better cognitive performance (Costa-Dookhan *et al.* 2020). In general, however, decisions about clozapine dose should be made based on assessment of clinical and side effects, not clozapine level.

Pharmacogenetic Profile

In recent years, several studies have linked genetic polymorphisms to either response to clozapine or the likelihood of experiencing side effects, such as weight gain and clozapine-induced agranulocytosis (CIA). The most important of these are single-nucleotide polymorphisms in human leukocyte antigen *(HLA)-DQB1* and *HLA-B* associated with CIA (Goldstein *et al.* 2014). CYP genetic variants have been associated with decreased response to clozapine, and polymorphisms in the gene for brain-derived neurotrophic factor (*BDNF*) have been found to be associated with improved response (Sriretnakumar *et al.* 2015). The Pro12Ala polymorphism of the peroxisome proliferator-activated receptor gene g2 (*PPAR*-g2) appears to predispose patients on clozapine to metabolic syndrome: patients with the Pro-Ala substitution had a 53.8% likelihood of having metabolic syndrome, whereas those with the Pro-Pro polymorphism had only a 16.3% likelihood (Fernandez *et al.* 2012). However, none of these findings has produced a

clinically useful pharmacogenomics tool for clinicians (Islam *et al.* 2021). Although not yet integrated into clinical practice, the pharmacogenetics of clozapine may soon help inform clinicians about the likelihood of a patient either responding to clozapine treatment or developing a concerning side effect.

Mechanism of Action

The effectiveness of antipsychotics was previously thought to be solely associated with D_2 receptor blockade, and induction of EPS was thought to be necessary for antipsychotic action. Clozapine's low rates of EPS but superior efficacy as an antipsychotic undermined and eventually overturned these ideas. The exact mechanism of clozapine's antipsychotic effect remains unknown, but several theories have been proposed. In the following discussion we describe the possible mechanisms of both clozapine's low EPS and its highly effective antipsychotic effect.

Dual 5-HT_{2A}/D_2 Antagonism

The low level of EPS from clozapine treatment (and many other SGAs) was thought to be due to its greater activity at the 5-HT_{2A} receptor than at the D_2 receptor (Meltzer and Massey 2011; Meltzer *et al.* 1989, 2003). This model, as laid out by Stahl (2013), is as follows: D_2 receptor antagonism in the mesolimbic pathway (projecting from the midbrain ventral tegmental area to the nucleus accumbens) reduces excessive dopamine signaling in the nucleus accumbens and reduces positive symptoms. However, D_2 receptor antagonism of the nigrostriatal pathway, which projects from the substantia nigra to the striatum of the basal ganglia, causes Parkinson-like involuntary movements, dystonias, and other EPS. Clozapine's antagonism of the 5-HT_{2A} receptor in the striatum results in increased local release of D_2, which results in relief from the EPS caused by D_2 antagonism. Similarly, in the tuberoinfundibular tract, which projects from the hypothalamus to the anterior pituitary gland, D_2 antagonism causes increased prolactin secretion, resulting in gynecomastia, galactorrhea, amenorrhea, and decreased libido. Local 5-HT_{2A} antagonism at the pituitary gland from SGAs increases local D_2 signaling and thus reverses the increase in prolactin secretion.

Although this characteristic of the SGAs may be associated with their relatively lower rates of EPS compared with FGAs, some evidence calls this into question. For instance, risperidone has high affinity for 5-HT_{2A} receptors yet also has high rates of gynecomastia and galactorrhea. Also, quetiapine produces very few EPS but has no specificity for 5-HT_{2A} receptors.

Low Percentage of D_2 Receptor Occupancy

Clozapine and some other SGAs have been shown to occupy less than 60% of D_2 receptors at therapeutic doses, in contrast to 75%-80% binding with the FGA class. This may explain the low rate of EPS with most SGAs.

Fast-Off D_2 Receptor Dissociation

Kapur and Seeman (2001) and others have proposed that the rapid dissociation of clozapine from the D_2 receptor could give rise to its low EPS and efficacy for psychosis. This fast dissociation or "loose binding" characteristic allows clozapine to be displaced by endogenous dopamine, thus allowing more physiological signaling than during treatment with most other antipsychotics. In their review, Kapur and Seeman noted that if D_2 receptor occupancy was high, EPS occurred even in the presence of strong 5-HT_{2A} antagonism, whereas rapid dissociation from the D_2 receptor in in vitro studies had the closest correlation with "atypicality."

Clozapine's Exceptional Efficacy

To date, clozapine remains the most effective antipsychotic in the clinician's arsenal. What could explain clozapine's superior efficacy? Let us examine two very similar antipsychotics, clozapine and its derivative, quetiapine. Clozapine and quetiapine have very similar pharmacological profiles, have the highest dissociation constants from the D_2 receptor, have fast-off dynamics at the D_2 receptor, and have high binding affinity to the 5-HT_{2A} receptor. However, the antipsychotic efficacy of quetiapine cannot match that of clozapine (McEvoy *et al.* 2006). What can explain clozapine's superior efficacy to all other antipsychotics? This remains one of the ongoing mysteries of treatment of schizophrenia. A few theories are discussed in the following subsections.

D_1:D_2 Equivalent Occupancy

The differences in efficacy between clozapine and quetiapine despite their similarities could be explained by the differential D_1:D_2 occupancy ratio between clozapine and other members of the SGA class. In a PET study using ^{11}C-SCH23390 and ^{11}C-raclopride to determine D_1 and D_2 receptor occupancy in patients with schizophrenia, clozapine was found to have the highest D_1:D_2 receptor occupancy ratio (0.88), compared with olanzapine (0.54), quetiapine (0.41), and risperidone (0.31) (Tauscher *et al.* 2004).

D_4 Receptor Binding

Clozapine also has a very high affinity for the D_4 receptor, which is widely distributed in the cortex and less so in striatal areas. It was thought that this D_4 binding could be the unique characteristic that gives clozapine its superior efficacy against psychosis. However, other agents with high D_4 receptor activity have failed to demonstrate antipsychotic activity.

Combination of Activity at Multiple Specific Receptor Types

None of the theories discussed thus far can explain the unique efficacy of clozapine for psychosis. Another possibility is that the unique signature of clozapine's receptor binding profile among the dopaminergic, serotonergic, adrenergic, histaminergic, and muscarinic receptors explains its unique efficacy. Clozapine may also have unknown activity at other receptors, such as glutamate, GABA, and neuropeptide receptors.

Metabolites

Clozapine's primary metabolite, norclozapine, is thought to possibly have a role in its antipsychotic effect because the metabolite represents 10%-90% of circulating active drug in patient serum (Wenthur and Lindsley 2013). However, trials of norclozapine have not demonstrated antipsychotic efficacy.

Indications and Efficacy

Acute Schizophrenia and Schizoaffective Disorder

Because of its side-effect profile, clozapine should not be administered as a first-line agent for schizophrenia or schizoaffective disorder. However, it remains the most effective antipsychotic available for treatment of schizophrenia and schizoaffective disorder. In a recent systematic quantitative meta-review of 112 meta-analyses, clozapine was found to be superior to FGAs and SGAs with regard to symptoms, relapse, hospitalization, mortality, and all-cause discontinuation (Wagner *et al.* 2021). This is consistent with numerous other studies, including large registry studies, indicating that clozapine surpasses all other oral antipsychotics in its efficacy (Tiihonen *et al.* 2017).

Treatment-Refractory Schizophrenia

Early studies suggested that clozapine was particularly effective in patients with more severe treatment-refractory forms of schizophrenia. This was important when it was discovered that clozapine was associated with a risk of agranulocytosis. Given that clozapine was viewed as an agent that might be helpful for patients who had failed to respond to other antipsychotics, a study was designed to test whether it could play a role in treatment of this population. As a result, a multicenter study was designed that compared clozapine with chlorpromazine in severely ill patients with treatment-refractory schizophrenia (Kane *et al.* 1988). Treatment-refractory illness was characterized based on the patient's history of drug non-responsiveness and failure to improve during a 6-week trial of up to 60 mg of haloperidol. Clozapine resulted in greater improvement in nearly every dimension of psychopathology. Thirty percent of the patients treated with clozapine met stringent improvement criteria, compared with only 4% of those treated with chlorpromazine. Other studies have suggested that the proportion of patients improving with clozapine treatment will be higher if clozapine is continued for a longer time. For example, a 16-week trial by Pickar *et al.* (1992) found a 38% improvement rate. A more recent report (Kane *et al.* 2001) found that 60% of patients with treatment-refractory illness improved after a 29-week trial on clozapine.

Two large trials compared clozapine with SGAs in individuals who had treatment-resistant illness. In the United States, the National Institute of

Mental Health's Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) compared clozapine with risperidone, olanzapine, or quetiapine in patients with schizophrenia who had failed to show response in an earlier phase of the study because of a lack of efficacy (Stroup *et al.* 2006). Clozapine was administered open label, whereas the other antipsychotics were administered double-blind. Patients assigned to clozapine had the lowest discontinuation rates, with 56% of patients taking clozapine discontinuing treatment, compared with 71% of those taking olanzapine, 86% of those taking risperidone, and 93% of those taking quetiapine. Clozapine-treated patients also showed greater symptom improvements than those receiving the other agents. A trial in the United Kingdom, the Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study-Band 2 (CUtLASS-2; Lewis *et al.* 2006), randomly assigned 136 patients who had responded poorly to two prior antipsychotics to either clozapine or an SGA selected

prior to randomization. Patients who received clozapine demonstrated greater improvement than those who received the comparison drugs.

Treatment-resistant schizophrenia is now generally agreed to mean schizophrenia that has failed to respond to two antipsychotic trials of sufficient dosage and duration (Correll and Howes 2021). A large body of evidence indicates that clozapine has an important role in the treatment of patients whose illness has failed to respond to either FGAs or other SGAs. Clozapine's advantages are clearest in patients whose illness failed to respond to FGAs but are still apparent in those whose illness responded inadequately to other SGAs. Because clozapine is associated with a risk of agranulocytosis and other side effects (summarized later in this chapter in the section "Side Effects and Toxicology"), patients should probably receive a trial of two other antipsychotics, one of which is an SGA, before receiving a trial of clozapine (Lehman *et al.* 2004a, 2004b; Marder *et al.* 2002; Miller *et al.* 2004).

Hostile and Aggressive Behavior in Schizophrenia

Clozapine may have other advantages for patients with schizophrenia. Several studies suggest that clozapine may decrease hostility and aggression more effectively than other agents. In a study of 157 inpatients (Citrome *et al.* 2001), clozapine produced greater reductions in scores on the hostility item from the Positive and Negative Syndrome Scale (PANSS) than did the FGAs and other SGAs. A study by Chengappa *et al.* (2003) found significant reductions in the rates of seclusion and restraint among patients with schizophrenia who had received clozapine during the first 3 years after its introduction. Other randomized studies have consistently found that patients treated with clozapine exhibit less hostility and less aggressive behavior than patients given comparator agents (Essock *et al.* 2000; Kane *et al.* 1988). A 2021 study of patients with a history of physical assaults and schizophrenia found that clozapine was more effective than olanzapine and haloperidol at reducing assaults (Krakowski *et al.* 2021). A 2020 study from Sweden found that clozapine was associated with a lower rate of violent offending than olanzapine (Bhavsar *et al.* 2020). These findings suggest that clozapine may be of particular benefit to patients with treatment-refractory illness who demonstrate hostile and aggressive behavior.

Schizophrenia Patients at High Risk for Suicide

Clozapine may also be a preferred agent for patients with schizophrenia who are at a higher risk for suicide. Large epidemiological studies have found that mortality from suicide is reduced among individuals taking clozapine (Reid *et al.* 1998; Walker *et al.* 1997). Meltzer and Okayli (1995) followed patients whose treatment was changed to clozapine and found a reduction in the number of serious suicide attempts as well as in expressed depression and hopelessness. Another convincing study was a comparison of clozapine and olanzapine in 980 patients with schizophrenia who were considered to be at risk for suicide. In that study, clozapine was more effective than olanzapine in reducing the risk of suicide (Meltzer 2002). In a Finnish study, SGAs were associated with decreased mortality from suicide in first-episode patients, whereas FGAs were associated with increased mortality. When clozapine, olanzapine, quetiapine, and risperidone were compared, only clozapine was found to have a strong anti-suicide effect (Kiviniemi *et al.* 2013).

Schizophrenia With Comorbid Substance Abuse

Although the effectiveness of clozapine in patients with comorbid substance abuse has not been demonstrated in randomized controlled trials, there is some supporting evidence from naturalistic studies. One retrospective study (Green *et al.* 2003) found that patients treated with clozapine were more likely than those treated with risperidone to abstain from alcohol and cannabis use. A prospective study (Green *et al.* 2007) found that patients treated with clozapine were often able to reduce their substance abuse. This finding was supported by other prospective studies (Brunette *et al.* 2006; Drake *et al.* 2000), indicating that clozapine is effective for reducing substance abuse.

Mania in Bipolar Disorder

Given that all available antipsychotics are effective in reducing manic symptoms, it is not surprising that clozapine is effective in bipolar mania. However, accumulating evidence suggests that clozapine is particularly effective for manic symptoms that are not responsive to other agents. McElroy *et al.* (1991) were among the first to observe clozapine's unique effects in patients with bipolar disorder. Subsequent studies have confirmed clozapine's effectiveness as monotherapy and as a supplementation medication for mania in bipolar disorder. In an open-label randomized trial in acutely manic patients (Barbini *et al.* 1997), clozapine was as effective as chlorpromazine and had a more rapid onset of action. Suppes *et al.* (1999) randomly assigned patients with treatment-resistant schizoaffective or bipolar illness to either supplemental clozapine or treatment as usual during a 1-year open-label trial. Among both groups of patients, those treated with clozapine demonstrated greater improvements.

Depression With Psychotic Features

Limited evidence suggests that clozapine is effective as monotherapy and as an adjunctive treatment for patients with major depressive disorder with psychotic features. This evidence is currently confined to case reports from relatively small numbers of cases (Ranjan and Meltzer 1996; Rothschild 1996).

Psychosis in Parkinson's Disease

Psychosis with delusions and hallucinations occurs in approximately 25% of patients with Parkinson's disease (Wolters and Berendse 2001). These symptoms frequently appear in patients who are receiving dopaminomimetic drugs but may also occur because of a cholinergic deficit. Three double-blind studies (The French Clozapine Parkinson Study Group 1999; Jones and Stoukides 1992; Parkinson Study Group 1999; Pollak *et al.* 2004) found that clozapine at dosages as low as 25-50 mg/day was effective in reducing psychotic symptoms. Moreover, these dosages were not associated with an increase in tremor and rigidity. A report from the American Academy of Neurology (Miyasaki *et al.* 2006) recommended clozapine as a preferred agent for psychosis in Parkinson's disease.

Schizophrenia in Children and Adolescents

A 2018 network meta-analysis found that clozapine was superior in efficacy to other antipsychotics for treatment of children and adolescents (Krause *et al.* 2018). It was also associated with substantial weight gain.

Augmentation Strategies in Partial Responders to Clozapine

Some studies have evaluated augmentation strategies for individuals who are partial responders to clozapine. A meta-analysis (Sommer *et al.* 2012) reviewed 29 double-blind randomized trials of agents used to augment the effects of clozapine. The most-studied antipsychotics added to clozapine were risperidone and aripiprazole, and the most-studied mood stabilizer was lamotrigine. Although some of the studies reported positive findings, none of the strategies was viewed as having adequate empirical support. Augmentation with electroconvulsive therapy (ECT) has been shown to be more promising, with a prospective, randomized study demonstrating a 50% response rate in clozapine-treated patients who received ECT, compared with 0% in those who remained on clozapine alone (Petrides *et* *al.* 2015). A survey among members of the Treatment Response and Resistance In Psychosis (TRRIP) working group reached consensus on recommending augmentation with ECT, amisulpride, or oral aripiprazole (Wagner *et al.* 2020).

Maintenance Therapy in Schizophrenia

Clozapine use has largely been confined to patients with treatment-refractory schizophrenia. As a result, clozapine has not been studied in traditional relapse prevention designs in which patients who are stable are randomly assigned to either clozapine or a comparator. Nevertheless, substantial data support clozapine's long-term effectiveness. Breier *et al.* (2000) evaluated the outcomes of 30 patients with schizophrenia who received clozapine for 1 year. Patients given clozapine experienced fewer relapses and rehospitalizations than they had in the year prior to being changed to clozapine. A study in the state hospitals in Connecticut compared patients who were assigned to clozapine with patients who were maintained on their usual antipsychotics (Essock *et al.* 2000). Although clozapine did not result in a greater likelihood of hospital discharge, patients who were treated with clozapine had a higher likelihood of remaining in the community following discharge. This finding supports the observation that clozapine is associated with a reduced risk of relapse compared with conventional antipsychotics.

A study from the U.S. Department of Veterans Affairs Cooperative Studies Program compared haloperidol and clozapine in patients with treatment-refractory schizophrenia (Rosenheck *et al.* 1997). This study was not designed as a relapse prevention trial but rather as a comparison of the two agents in individuals whose illness had responded poorly to conventional therapy. However, the 1-year study is somewhat informative about the usefulness of the two drugs in patients living in the community. Fifty-seven percent of the patients taking clozapine completed the study, compared with only 28% of the patients taking haloperidol ($P < 0.001$). Using 20% improvement on the PANSS as the criterion for response, the investigators found that 42% of patients treated with clozapine and 31% of patients treated with haloperidol were responders ($P = 0.09$). In addition, clozapine-treated patients had fewer mean days of hospitalization (143.8 days) compared with haloperidol-treated patients (168.1 days; $P = 0.03$).

Other Indications

Clozapine may also help patients with polydipsia-hyponatremia syndrome (Canuso and Goldman 1999). Patients with this syndrome tend to intoxicate themselves through excessive water drinking, and the resultant hyponatremia may result in seizures.

Clozapine has historically been used to treat tardive dyskinesia (TD), although it has not been formally studied extensively for this purpose. In a 1991 review, Lieberman *et al.* (1991) reviewed eight small studies and conducted their own study of 30 patients with TD and found that in 50% of patients, clozapine reduced TD symptoms by approximately 43% (Lieberman *et al.* 1991). Other studies found equivocal results; however, in no study did clozapine worsen TD. Kimiagar *et al.* (2012) found that TD symptoms were reversed with a combination of clozapine, clonazepam, and tetrabenazine. Clozapine's mechanism of action for reducing TD remains unknown.

Side Effects and Toxicology

Hematological Effects

The side effects of clozapine make it one of the most challenging medications for psychiatrists to prescribe. The main factor that limits its use is the potential serious side effect of CIA. *Agranulocytosis* is defined as a drop in absolute neutrophil count (ANC) to levels below 500/mm^3. In 1975, there were 17 cases of agranulocytosis in Finland, and widespread use of the medication for the treatment of schizophrenia was temporarily halted (Amsler *et al.* 1977; de la Chapelle *et al.* 1977).

Agranulocytosis is a potentially lethal side effect that occurs in less than 1% of patients treated with clozapine in the United States (Alvir *et al.*

1993); therefore, all patients who are taking clozapine are entered into a national registry known as the Clozapine Risk Evaluation and Mitigation Strategy (REMS) Program (www.clozapinerems.com). Through this national registry, patients are prescribed the medication only if their ANC count shows no signs of clinically meaningful suppression (Honigfeld 1996). The morbidity and mortality of clozapine-treated patients over a 5-year period was reviewed in 99,502 patients registered through the previous Clozaril National Registry (Honigfeld *et al.* 1998). Among these patients, 2,931 (2.95%) developed leukopenia (WBC count < 3,500/mm^3), and 382 (0.38%) developed agranulocytosis (ANC < 500/mm^3). Twelve of the cases of agranulocytosis (0.012%) were fatal.

When clozapine treatment is discontinued on identification of marked leukopenia, patients usually recover within 14-24 days and without any long-term consequences. However, rechallenging patients who have experienced agranulocytosis almost always leads to recurrence of the problem. The onset of the second episode is more aggressive than that of the first. In nine patients who were known to be rechallenged, the average time to onset of the second episode was 10 weeks shorter (14 weeks) than for the first episode (24 weeks) (Safferman *et al.* 1992). Agranulocytosis has been successfully treated by discontinuing the medication, providing supportive measures, and administering granulocyte colony-stimulating factor, a medication commonly prescribed to patients with medical illnesses that precipitate WBC count suppression (Raison *et al.* 1994; Weide *et al.* 1992; Wickramanayake *et al.* 1995).

In January 2006, Novartis and the FDA issued a notification to clinicians about modifications to the recommended monitoring schedule for patients receiving clozapine (Novartis Pharmaceuticals 2010). This document continues to be useful; however, in October 2015, the guidelines were updated under a unifying national registry, the Clozapine REMS Program (U.S. Food and Drug Administration 2015). In order to prescribe

clozapine, the prescribing physician, dispensing pharmacy, and patient must be registered with the REMS Program. Under the new monitoring guidelines, a patient beginning clozapine treatment must have a baseline

ANC count of no less than 1,500/mm^3 (1,000/mm^3 if the patient has benign ethnic neutropenia). If, during clozapine treatment, a patient's ANC drops below 1,000/mm^3, clozapine must be interrupted; for patients with benign ethnic neutropenia, treatment must be interrupted if their ANC drops below 500/mm^3. Weekly ANC levels must be obtained for 6 months, at which time the frequency can be reduced to every 2 weeks provided that treatment and monitoring have not been interrupted and that WBC counts and ANCs have remained within acceptable ranges. After 1 year, monitoring can be reduced to monthly blood tests.

Cardiac Effects

Clozapine, like other antipsychotic drugs, carries an FDA black box warning against use in elderly patients with dementia-related psychosis, because of an increased risk of death due primarily to cardiovascular and infectious causes (HLS Therapeutics 2023).

Well-known side effects of clozapine on the cardiovascular system include tachycardia, bradycardia, syncope, and orthostatic hypotension. Tachycardia is thought to be attributable to the anticholinergic activity of the medication at the M_2 receptor, leading to vagal nerve inhibition; hypotension is due to a-adrenergic blockade; and bradycardia is thought to be neurally mediated reflex bradycardia, also known as the vasovagal response.

The most worrisome forms of cardiovascular toxicity, however, are clozapine-associated myocarditis and cardiomyopathy. A 2020 meta-analysis that included more than 250,000 patients found that myocarditis occurred in approximately 7 of 1,000 people treated with clozapine and had an absolute death rate of 4 in 10,000 people (Siskind *et al.* 2020). Cardiomyopathy occurred in 6 of 1,000 people, with a death rate of 3 in 10,000.

The detection of cardiac toxicity is challenging because its manifestations (i.e., tachycardia, fatigue, and orthostatic hypotension) are frequently observed in patients treated with clozapine, particularly when the dosage is altered (Lieberman and Safferman 1992). The poor specificity of signs for cardiac toxicity demands that patients with any personal or family history of heart disease be identified, and the threshold for medical evaluation of patients developing respiratory and cardiovascular symptoms must be low (Wooltorton 2002). Therefore, we recommend monitoring patients' C-reactive protein, eosinophil count, and troponins on a weekly basis for the first 4 weeks of therapy. Etiology of the myocarditis and cardiomyopathy remains unclear.

To monitor for hypotension caused by clozapine, we also recommend a slow upward titration of the medication and monitoring of orthostatic vital signs during the first weeks of therapy. Patients should be educated about the risk of orthostatic hypotension and taught to rise slowly from supine positions. Concomitant treatment with b-blocking agents may be necessary for persistent tachycardia. However, b-blockers may exacerbate the hypotensive effects of clozapine and should be used cautiously.

Metabolic Effects

Weight Gain

Weight gain has been observed in both premarketing and postmarketing trials of clozapine (Henderson 2001; Simpson and Varga 1974; Wirshing *et al.* 1998, 1999). Allison *et al.* (1999) performed a meta-analysis of the weight-gain data in short-term trials of medications. The average weight gain observed with clozapine was 4.45 kg, which exceeded the weight gain observed with all other medications in the study, including the conventional agent thioridazine (3.19 kg), a medication known for its weight-gain liability. The weight gain observed with clozapine seems to occur for a prolonged period--up to 40 weeks. In one naturalistic study, Henderson (2001) observed patients in a clozapine clinic for 5 years and noted weight gain occurring for up to 46 months in some patients.

Phase II of the CATIE provided an opportunity to compare weight gain among patients assigned to clozapine, olanzapine, risperidone, and quetiapine (McEvoy *et al.* 2006). The numbers of patients assessed in the analyses were small, with only 45 patients in the clozapine group, 17 in the olanzapine group, 14 in the quetiapine group, and 14 in the risperidone group. Although the differences in weight gain among these agents were not statistically significant, they were interesting, with patients taking clozapine gaining a mean of 0.5 lb/month, compared with 1.0 lb for olanzapine, 0.4 lb for quetiapine, and 0.5 lb for risperidone.

Diabetes

The weight gain observed with clozapine can place patients at risk for significant health problems. Diabetes is naturally the most concerning potential sequela of this weight gain. Numerous case reports have linked clozapine with new-onset diabetes (Wirshing *et al.* 1998). In Henderson's (2001) naturalistic study of 81 clozapine-treated patients observed over a 5-year period, 36.6% of patients developed diabetes.

Patients treated with clozapine should be routinely screened for diabetes and other metabolic abnormalities, including elevated lipid levels. Patients with risk factors for diabetes should be monitored more closely. Reports and clinical experience suggest that in a case of antipsychotic-associated diabetes or diabetic ketoacidosis, discontinuing the antipsychotic agent may lead to reversal of the hyperglycemia and diabetes. During clozapine therapy, we recommend monitoring fasting glucose, cholesterol, and lipid levels at baseline and every 6 months thereafter.

Prevention of weight gain with clozapine, through nutrition and diet counseling, is recommended. Caloric restriction and exercise for 30 minutes/day should be recommended. Screening questions by physicians that we find useful include the following: "Have you noticed if your belt or pants size has changed?" "Have you noticed an increase in thirst or urinary frequency?"

Dyslipidemias

Clozapine treatment is associated with dyslipidemias, including elevations in triglycerides and cholesterol, particularly low-density lipoprotein cholesterol (McEvoy *et al.* 2006; Wirshing *et al.* 2002a).

In 2004, in response to growing concern that most antipsychotic medications may be associated with weight gain and other metabolic changes, the American Diabetes Association and other groups published a set of guidelines for monitoring weight, glucose, and lipids (American Diabetes Association *et al.* 2004). A very comprehensive literature review was conducted by Marder *et al.* (2004) to guide clinicians in monitoring weight, glucose, lipids, and other parameters of physical health in patients with schizophrenia. Labels were changed for all antipsychotic medications, including clozapine, regarding these metabolic risk factors.

Seizures

A well-known side effect of clozapine treatment is the risk for seizures, which are thought to occur in 5%-10% of patients treated with this medication (Welch *et al.* 1994). The cause of seizures is unclear, but rapid escalations in dosage and possibly high plasma levels of clozapine may account for their development (Klimke and Klieser 1995). Clozapine-associated seizures occur most often at dosages greater than 600 mg/day. The relationship between clozapine plasma levels and seizures is somewhat inconsistent in the literature (Simpson and Cooper 1978; Vailleau *et al.* 1996).

The anticonvulsant agents sodium valproate, gabapentin, and topiramate have been used successfully to treat clozapine-induced seizures (Navarro *et al.* 2001; Toth and Frankenburg 1994; Usiskin *et al.* 2000). Topiramate has an advantage over sodium valproate because it is associated with very little weight gain. In cases in our clinic in which patients develop seizures while taking clozapine, we institute rapid loading with anticonvulsant medication and temporarily discontinue the clozapine treatment. We then slowly reintroduce and re-titrate the clozapine once the patient is taking an adequate dose of anticonvulsant medication.

Anticholinergic Effects

Anticholinergic side effects resulting from clozapine's muscarinic receptor antagonism include sedation, weight gain, dry mouth, constipation, and, in some cases, ileus or bowel obstruction. Constipation can be a difficult but important side effect to manage in severely mentally ill individuals, who may not complain about the problem until a medical emergency, such as acute bowel obstruction, occurs. In institutional settings and in prisons, where patients may have little access to exercise and where their fluid intake levels are not monitored, constipation from clozapine can be serious or even fatal (Drew and Herdson 1997; Hayes and Gibler 1995; Levin *et al.* 2002). Typically, constipation can be avoided with proactive modifications to patients' diets and education about adequate fluid intake and exercise. Our preferred medical treatment is prophylactic therapy with sorbitol. We are less inclined to recommend treatments involving bulking agents, particularly in the setting of poor fluid intake. High-fiber diets can also be beneficial.

Other Side Effects

Sedation is one of the most difficult and common side effects of clozapine to manage. Patients often do not want their dosages increased in the setting of increased sedation and will complain of sedation as one of the most annoying consequences of clozapine treatment (Angermeyer *et al.* 2001). In our experience, sedation is usually the limiting factor controlling both the rate at which the dosage of clozapine can be increased and the maximum dosage the patient can tolerate. However, no rigorous studies have been published.

There have been several reports of respiratory arrest or depression during the early stages of treatment with clozapine (HLS Therapeutics 2023). Two of the patients who experienced respiratory arrest were concomitantly taking benzodiazepines.

Sialorrhea is a commonly reported side effect of clozapine (occurring in more than 50% of patients) that can be problematic for patients. Its etiology is unclear, but it does not seem to be caused by the dopamine blockade. It may be mediated through a-adrenergic receptor blockade. Case series and small pilot studies indicate that treating sialorrhea with antiadrenergic agents, such as the clonidine patch; anticholinergic agents, such as benztropine and intranasal ipratropium bromide; or atropine ophthalmic drops administered sublingually may be successful (Calderon *et al.* 2000). We generally recommend that patients sleep with a towel on their pillow because this side effect seems to be most bothersome during the night. Unfortunately, the use of concomitant antiadrenergic or anticholinergic agents adds to the potential side effect burdens of hypotension and constipation, respectively.

Neuroleptic malignant syndrome, a syndrome of unknown etiology that includes hyperthermia, autonomic instability, and severe rigidity, has been reported in several patients treated with clozapine (Anderson and Powers 1991). The etiology of neuroleptic malignant syndrome occurring in the context of clozapine use, as well as that occurring with conventional antipsychotic use, remains unclear.

Hepatotoxicity has been reported with clozapine, especially in the setting of polypharmacy (Macfarlane *et al.* 1997; Wirshing *et al.* 1997). Asymptomatic elevation of transaminase levels was observed most often, affecting between 30% and 50% of patients treated with clozapine. Icteric hepatitis was uncommonly seen in Macfarlane et al.'s (1997) review of clozapine-related hepatotoxicity and noted in 84 of 136,000 patients (0.06%). Fatal acute fulminant hepatitis has been documented in 2 patients (0.001%). Although serious toxicity is rare, prescribers of clozapine should be aware of its hepatotoxic potential.

Sexual side effects, including priapism and impotence, have been reported with clozapine. Urinary retention and bladder dysfunction can also result from clozapine. In a study that surveyed patients' sexual side effects, we found that patients taking clozapine actually had fewer sexual complaints than those taking other antipsychotic medications (fluphenazine and risperidone) (Wirshing *et al.* 2002b).

Dizziness, vertigo, and headache have also been reported with clozapine (HLS Therapeutics 2023).

Clozapine has been shown to induce de novo obsessive-compulsive symptoms (OCS). In a naturalistic study following 543 patients, 38.9% of those taking clozapine reported OCS, compared with 20.1% of those taking olanzapine and 23.2% of those taking risperidone (Scheltema Beduin *et al.* 2012). Two case studies of patients with bipolar disorder taking clozapine reported a clear temporal relationship between initiation of clozapine and OCS (Lemke and Bustillo 2013). The severity of OCS appears to be dosage related, which suggests that clozapine dosage reduction may be effective

(Kim *et al.* 2020). There is support for treating these symptoms with selective serotonin reuptake inhibitors, clomipramine, and aripiprazole. In our experience, patients with OCS often benefit from combining medications with cognitive-behavioral therapy for OCD.

Although this daunting array of side effects--along with the management of the risk of agranulocytosis--makes the treatment of patients with clozapine complex, it is common for patients to report a sense of relief from the dysphoric moods they experienced with conventional drugs. Additionally, the freedom from EPS may account for the enhanced sense of well-being in patients treated with clozapine.

Discontinuation and Reinitiation (Rechallenge)

In their 2013 review, Nielsen *et al.* (2013) posited that clozapine should be discontinued in all cases of agranulocytosis (ANC < 500/mm^3), myocarditis, and cardiomyopathy

but should not be discontinued for known benign side effects such as eosinophilia, benign neutrophilia or leukocytosis, idiopathic sinus tachycardia, or benign hyperthermia. Seizures should not be an absolute contraindication to clozapine treatment because they may be managed with initiation of an anticonvulsant, either to prevent or to stabilize seizures prior to initiation of clozapine.

Historically, if a patient's WBC decreased below 2,000/mm^3 or their ANC decreased below 1,000/mm^3, clozapine was discontinued and the patient was regarded as non-rechallengeable--that is, re-initiation of clozapine should not be attempted. With new FDA regulations implemented in October 2015, clinicians were given the freedom to evaluate each patient on a case-by-case basis and to weigh the relative risk of psychosis with risk of agranulocytosis. If and when a clinician opts to restart clozapine in a patient, regardless of the circumstance, they must begin at 12.5 mg orally once or twice daily and titrate upward gradually. If the patient has not experienced adverse effects from clozapine in the past, the re-initiation dosage may be titrated upward more rapidly than their initial titration.

Drug-Drug Interactions

As previously mentioned, clozapine is predominantly metabolized by CYP1A2, although CYP2D6 and CYP3A3/4 also contribute to its metabolism (Buur-Rasmussen and Brosen 1999). Smoking, which induces CYP1A2, lowers clozapine plasma levels, and dosages of clozapine up to twice the normal dosage may be required to maintain a therapeutic serum level. Use of phenytoin and rifampin may also decrease clozapine plasma concentrations (HLS Therapeutics 2023). Fluvoxamine and ciprofloxacin, potent inhibitors of CYP1A2, dramatically increase plasma levels of clozapine (Heeringa *et al.* 1999; U.S. Food and Drug Administration 2023), and on occasion, adverse effects are seen (Koponen *et al.* 1996). Other reports suggest that inhibitors of CYP2D6, including paroxetine and fluoxetine, can elevate clozapine levels (Joos *et al.* 1997; Spina *et al.* 1998). In general, if the patient initiates a strong CYP1A2 inhibitor, use one-third of their normal clozapine dosage. For those initiating moderate or weak CYP1A2 inhibitors or CYP2D6 or CYP3A3/4 inhibitors, consider decreasing their clozapine dosage. If they initiate strong CYP3A3/4 inducers or moderate or weak CYP1A2 inducers, monitor for decreased effectiveness and consider increasing their clozapine dosage if necessary (HLS Therapeutics 2023). CYP-related problems can be avoided by monitoring clozapine plasma levels while gradually increasing clozapine from a low starting dosage. Clozapine should not be used together with other drug products known to have the potential to suppress bone marrow function. Clozapine may potentiate the hypotensive effects of antihypertensive and anticholinergic drugs (HLS Therapeutics 2023).

Conclusion

Clozapine maintains an important place in the treatment of severe psychosis. Side effects, including agranulocytosis, cardiomyopathy, seizures, sedation, and weight gain, make it the most difficult antipsychotic to prescribe. For this reason, clozapine should be reserved for patients who have failed to respond to one or more other antipsychotics. On the whole, however, this very effective treatment is underutilized in most communities, which is unfortunate because a patient's illness should never be deemed "treatment refractory" or the patient labeled a "partial responder" until the individual has received an adequate trial of clozapine.

CHAPTER 27

Olanzapine

Jacob S. Ballon, M.D., M.P.H.

Julio C. Nunes, M.D.

Khalid Salaheldin, M.D.

History and Discovery

The story of specific antipsychotic medications for patients with schizophrenia and other severe psychiatric illnesses began in the early 1950s, when chlorpromazine was first given to psychotic patients in France (Delay and Bernitzer 1952). The antipsychotic qualities of this compound, as well as its "tranquilizing" effect, were dramatic and substantial. Studies performed around the world during the 1950s showed the usefulness of this new compound and of the others that followed. Multicenter trials of antipsychotic medications found that the approved medications were substantially and significantly better than placebo (Guttmacher 1964), and, despite the range of chemical structures, their clinical effects were similar. In addition, the need to investigate these new medications for psychiatric illness led to improved clinical trial methodology for the field. During the 1960s, randomized and placebo-controlled trials became the standard for assessing the new medications for schizophrenia and led to the adoption of antipsychotic medications as the standard somatic treatment for this condition.

Over time, however, the adverse effects of these medications began to be recognized as more troublesome. For example, many patients complained of medication-induced parkinsonism, dystonias, slowed thinking, blunted affect, akathisia, and tardive dyskinesia. These side effects were uncomfortable for patients taking the medications and, in many cases, led to poor treatment adherence. Seeking ways to achieve the same treatment benefits with fewer side effects, investigators at Eli Lilly began to screen numerous compounds for potentially useful psychotropic properties. In 1990, the company applied for and received a patent for the compound olanzapine. This compound had many structural similarities to clozapine, which in 1989 had been approved for use in treating refractory schizophrenia. Hailed as a novel second-generation antipsychotic (SGA) drug, clozapine was thought to have potential for schizophrenia, mania, and anxiety and was noted for both its efficacy and its lack of neurological side effects.

Olanzapine was first given to patients with schizophrenia in 1995 (Baldwin and Montgomery 1995). The patients in that study experienced a substantial decrease in their symptoms while receiving 5-30 mg/day of the compound. The researchers noted a low degree of extrapyramidal side effects (EPS), although they became concerned regarding the elevation of liver enzymes, for which one patient had to discontinue the study. Despite this, the initial testing of olanzapine had useful results and led to a program of three pivotal trials of the drug. These first three controlled studies compared olanzapine (at two fixed dosages, 1 mg/day and 10 mg/day) against placebo (Beasley *et al.* 1996a); olanzapine at three fixed dosages (low, medium, or high) against olanzapine at 1.0 mg/day or haloperidol at 15 mg/day or placebo (Beasley *et al.* 1996b); and olanzapine against haloperidol in a large international study (Tollefson *et al.* 1997). The positive results for olanzapine led to FDA approval in 1997 and to subsequent widespread use in the United States and around the world.

Structure-Activity Relations

Olanzapine is a thiobenzodiazepine derivative that bears a close structural resemblance to clozapine. Its formal chemical name is 2-methyl-4-(4-methyl-1-piperazinyl)-10*H*-thieno[2,3-*b*][1,5]benzodiazepine. Structurally, olanzapine differs from clozapine by two additional methyl groups and the lack of a chloride moiety (Figure 27-1). The in vitro receptor binding profiles of olanzapine and clozapine are relatively similar; according to the package insert, olanzapine is known to have a high affinity for dopaminergic ($D_{1\text{-}4}$), serotonergic (5-$HT_{2A/2C}$, 5-HT_6), histaminergic (H_1), and a-adrenergic (a_1) receptors, with moderate affinity for muscarinic ($M_{1\text{-}5}$) receptors and weak activity at benzodiazepine, g-aminobutyric acid A ($GABA_A$), and b-adrenergic receptors (Eli Lilly 2021).

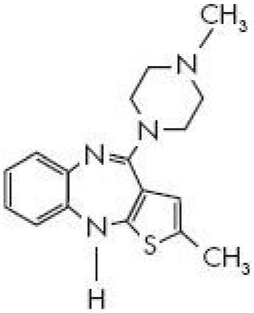

FIGURE 27-1. Chemical structure of olanzapine.

Pharmacological Profile

In vitro and preclinical behavioral studies of olanzapine predicted significant antipsychotic activity with a low propensity to induce EPS. Because clozapine is the prototype for SGA action, it serves as the yardstick for "atypicality" of comparator compounds. Despite widespread general use of the term *atypical* to refer to any antipsychotic developed after clozapine, the term was originally coined to connote medications with an EPS risk no greater than that of placebo. Although olanzapine does carry a lower risk of tardive dyskinesia than do many other antipsychotics, its risk is still appreciably greater than that of placebo, and therefore the term *atypical* has fallen out of fashion (Farah 2013).

One property that may lower a compound's risk of EPS is nonselective binding of dopamine receptors. Classical antipsychotics selectively block dopamine D_2-like (D_2, D_3, and D_4) receptors over D_1-like (D_1 and D_5) receptors--for example, haloperidol has a D_2:D_1 binding ratio of 25:1. Clozapine nonselectively binds all five dopamine

receptor subtypes, with a D_2:D_1 ratio of 0.7:1, whereas olanzapine is only partially selective for the D_2-like group, with a D_2:D_1 ratio of approximately 3:1, intermediate between those of haloperidol and clozapine.

In animal models predictive of antipsychotic efficacy, olanzapine produces effects indicating dopamine antagonism, with a low propensity to produce EPS. For example, in rats, olanzapine reduces climbing behavior induced by apomorphine and antagonizes stimulant-induced hyperactivity, both characteristic of antipsychotic effects. The ratio of the dosage needed to produce catalepsy to the dosage needed to inhibit conditioned avoidance is higher for olanzapine than for conventional agents (Moore 1999).

An additional mechanism whereby dopamine antagonists may exert antipsychotic effects with minimal EPS is through selective activity in the A10 dopaminergic tracts from the ventral tegmentum to mesolimbic areas compared with effects antagonizing the A9 nigrostriatal projections that mediate EPS. Olanzapine in chronic administration, like clozapine, selectively inhibits firing of A10 neurons without significant inhibition of A9 tracts (Stockton and Rasmussen 1996a). Olanzapine shows increased c-Fos activity in the nucleus accumbens relative to the dorsolateral striatum, thus demonstrating selective blockade of the mesolimbic dopamine tract compared with the nigrostriatal tract (Robertson and Fibiger 1996).

Another theory regarding olanzapine's efficacy considers its fleeting effects at the D_2 receptor, coupled with the regional selectivity of these compounds (Seeman 2002). Olanzapine's D_2 receptor occupancy saturation--which has been shown to be intermediate between that of clozapine and that of haloperidol--may be responsible for its decreased risk of EPS (Tauscher *et al.* 1999).

Amphetamine administration in rats is often used as a model for psychosis. The sympathomimetic activity and dopamine release provide a target for testing antipsychotic medications. Olanzapine disrupts the activity of amphetamines in rats (Gosselin *et al.* 1996). It was shown in a rat model to decrease dopamine release in the A10 dopaminergic neurons of the ventral tegmentum to a greater extent than in the A9 dopaminergic neurons of the striatum after chronic administration and after an amphetamine challenge (Stockton and Rasmussen 1996a, 1996b). Another model of psychosis in rats is produced by administration of the glutamatergic *N*-methyl-D-aspartate (NMDA) receptor antagonist phencyclidine. Chronic phencyclidine use in humans is associated with symptoms similar to those in schizophrenia, including negative symptoms, thus making it a putative model for schizophrenia (Krystal *et al.* 1994). Olanzapine has been shown to decrease the hyperactivity of NMDA receptors under chronic phencyclidine administration, which may have a bearing on its effect on negative symptoms (Ninan *et al.* 2003). With chronic administration, glutamatergic activity continues to be affected by olanzapine (Jardemark *et al.* 2000). Despite these findings, olanzapine has no direct affinity for the NMDA receptor (Stephenson and Pilowsky 1999).

Receptor-binding studies show that olanzapine has a broad range of neurotransmitter effects (Bymaster *et al.* 1996). Although it has potent muscarinic M_{1-5} receptor affinity in vitro (another contributor to putative anti-EPS effects), in practice few patients treated with olanzapine experience clinically significant anticholinergic side effects. a_1-Adrenergic and H_1 histaminergic antagonism contributes to olanzapine's adverse-effect profile of orthostatic hypotension (a_1), sedation (H_1), and possibly weight gain (H_1). Olanzapine, like other SGAs, has a higher affinity for 5-HT_2 receptors than for D_2 receptors (Kapur *et al.* 1999). There is also indirect evidence that olanzapine blocks 5-HT_{2C} receptors (Sharpley *et al.* 2000). Olanzapine has little or no effect on a_2- and b-adrenergic, H_2, nicotinic, GABA, opioid, sigma, or benzodiazepine receptors.

Pharmacokinetics and Disposition

Olanzapine is well absorbed after oral administration, with peak concentrations typically occurring 4-6 hours after ingestion. Approximately 40% of a given dose undergoes first-pass metabolism and therefore does not reach the systemic circulation, and food has little effect on olanzapine's bioavailability (Eli Lilly 2021).

Two bioequivalent oral formulations of olanzapine are currently available: a standard oral tablet and an oral disintegrating tablet. Oral disintegrating tablets dissolve rapidly in saliva in the mouth and are then swallowed, and absorption of olanzapine occurs through the gut. Oral disintegrating tablets are favored by some because they allow the clinician to verify that the medication was taken. Markowitz *et al.* (2006) noted that although oral disintegrating tablets are absorbed slightly more rapidly than the standard oral tablets, the onset of effect is approximately the same, regardless of whether an orally disintegrating tablet or a standard oral tablet is administered. After a 12.5-mg oral dose of ^{14}C-labeled olanzapine, approximately 57% of the radiocarbon is recovered in urine and 30% in feces. In vitro studies suggest that olanzapine is approximately 93% protein bound, binding primarily to albumin and a_1-acid glycoprotein (Kassahun *et al.* 1997).

Olanzapine is available as an intramuscular preparation, intended for treatment of the acute agitation typically seen in schizophrenia or in acute manic episodes of bipolar disorder. The peak plasma concentration is typically reached between 15 and 45 minutes after administration. The potency of intramuscular olanzapine is nearly five times greater than that of the orally administered drug, based on plasma levels. Clinical antipsychotic effect onset with intramuscular olanzapine is evident within 2 hours of administration, with benefits lasting for at least 24 hours (Kapur *et al.* 2005).

Olanzapine is also available in a long-acting injectable (LAI) preparation composed of a dihydrate form of olanzapine pamoate (Eli Lilly 2014). As a dihydrate molecule, it is less soluble in water than a monohydrate and thus has the longer half-life required for a depot formulation. This formulation is designed to be administered once every 4 weeks. As the pamoate moiety converts to olanzapine rapidly in the bloodstream, extreme caution must be used to inject directly into a muscle, and patients must be observed for 3 hours after injection to monitor for delirium or sedation that could result from accidental injection into vasculature (Eli Lilly 2021).

Finally, olanzapine is available in two different combined preparations. The olanzapine/fluoxetine combination (OFC) tablet provides fixed doses of olanzapine and fluoxetine for treatment of bipolar depression (Eli Lilly 2009). Overall, few pharmacokinetic changes result from adding fluoxetine to olanzapine, and those that do occur are generally related to cytochrome P450 (CYP) 2D6 inhibition. There is no change in the overall half-life of olanzapine. Although minor yet statistically significant changes occur in the concentration of olanzapine when it is coadministered with fluoxetine, these changes are not *clinically* significant and do not alter the side-effect profile of olanzapine (Gossen *et al.* 2002). Olanzapine is also available in a combination with samidorphan (Alkermes 2021), an opiate antagonist that is FDA approved for use in the same conditions as olanzapine. The addition of samidorphan has been shown to help decrease the risk of weight gain compared with olanzapine alone, with no changes in pharmacokinetics of the olanzapine (Martin *et al.* 2019).

Olanzapine is extensively metabolized to multiple metabolites, but primarily to 10-*N*-glucuronide and 4'-*N*-desmethylolanzapine (Macias *et al.* 1998). In vitro studies examining the oxidative metabolism of olanzapine suggest that CYP1A2 is the enzyme primarily responsible for the formation of 4'-*N*-desmethylolanzapine, flavin-containing monooxygenase-3 (FMO3) is responsible for the formation of 4'-*N*-oxide olanzapine, and CYP2D6 is the primary enzyme responsible for the formation of 2-hydroxymethyl olanzapine (Ring *et al.* 1996b). Although CYP1A2 appears to be a major route of metabolism, olanzapine clearance in one study was not significantly correlated with the salivary paraxanthine-to-caffeine ratio (thought to be a measure of CYP1A2 activity) (Hagg *et al.* 2001). Another analysis, however, found that the 4'-*N*-desmethylolanzapine-to-olanzapine plasma metabolic ratio significantly correlated with olanzapine clearance (Callaghan *et al.* 1999). Olanzapine pharmacokinetic parameters do not differ significantly between extensive and poor metabolizers of CYP2D6 (see Hagg *et al.* 2001).

Olanzapine shows linear pharmacokinetics within the recommended dosage range (Callaghan *et al.* 1999). Mean half-life is 36 hours, mean clearance is 29.4 L/hour, mean volume of distribution is 19.2 L/kg, and area under the concentration-time curve over 24 hours ($AUC_{0\text{-}24}$) is 333 ng*hour/mL. The half-lives of the two major metabolites (4'-*N*-desmethylolanzapine and 10-*N*-glucuronide) are 92.6 and 39.6 hours, respectively (Macias *et al.* 1998). Other analyses also have found the mean half-life of olanzapine to be approximately 30 hours and the mean apparent clearance to be approximately 25 L/hour (Callaghan *et al.* 1999; Eli Lilly 2021; Kassahun *et al.* 1997). Once-daily administration of olanzapine produces steady-state concentrations in about 1 week that are approximately twofold higher than concentrations after a single dose (Callaghan *et al.* 1999).

Clearance of olanzapine is approximately 25%-30% lower in females than in males, based on results of population pharmacokinetic analyses (Callaghan *et al.* 1999; Patel *et al.* 1996). A study of 20 male and 7 female patients with schizophrenia receiving olanzapine also found that females had higher trough concentrations after receiving 1 week of olanzapine 12.5 mg/day (Kelly *et al.* 1999). Despite the differences in clearance and plasma levels, there is no difference between sexes in the incidence of EPS or other movement disorders (Aichhorn *et al.* 2006).

Olanzapine's pharmacokinetics in elderly persons and in children differ from those in other adults. In elderly individuals, olanzapine clearance is approximately 30% lower than in younger individuals, and the half-life is approximately 50% longer (Callaghan *et al.* 1999; Patel *et al.* 1996). A study of eight children and adolescents (ages 10-18 years) found pharmacokinetic parameters similar to those reported in nonsmoking adults, with an average T_{max} (time required to reach the maximal plasma concentration) of 4.7 hours, an average apparent oral clearance of 9.6 L/hour, and an average half-life of 37.2 hours (Grothe *et al.* 2000). The highest concentrations were seen when smaller-sized patients received dosages greater than 10 mg/day; therefore, dosing should take into consideration the size of the child.

Impairment in either hepatic or renal function has not been associated with altered olanzapine disposition. In a study of four healthy individuals and eight patients with hepatic cirrhosis, no significant differences in olanzapine pharmacokinetics were found, although urinary concentrations of olanzapine 10-*N*-glucuronide were increased in patients with cirrhosis. A study comparing olanzapine pharmacokinetics in six subjects with normal renal function, six subjects with renal failure who received an olanzapine dose 1 hour before hemodialysis, and six subjects with renal failure who received an olanzapine dose during their 48-hour interdialytic interval did not find any significant differences. These data suggest that olanzapine dosage does not need to be adjusted in patients with renal or hepatic disease (Callaghan *et al.* 1999).

Mechanism of Action

Regarding olanzapine's mechanism of action in the treatment of schizophrenia, it should be noted that no established molecular mechanism can unify the symptoms of schizophrenia. No precise animal or in vitro model for the illness exists, nor is there a consensus on its precise etiology or pathophysiology. Numerous neurochemical hypotheses have been proposed, including theories implicating abnormalities in dopaminergic, glutamatergic, serotonergic, and other systems, such as neurotensin (Boules *et al.* 2007) or neuregulin (Benzel *et al.* 2007). However, the discovery that multiple receptor types exist for each neurotransmitter has added many layers of complexity to the search for explanations regarding the root causes of schizophrenia. Thus, it is no longer possible to use broad terms such as "increased dopamine" when discussing ideas about the etiology of the disorder.

Despite these caveats regarding our rudimentary knowledge of the nature of schizophrenia, it is important to note that all approved antipsychotic medications have a significant effect on the dopaminergic system, largely through the blockade of D_2 receptors (Kapur and

Remington 2001). Even though there are substantial differences in D_2 receptor affinity among the traditional antipsychotics and the SGAs, they all are either full antagonists or partial agonists at the D_2 receptor. Of interest is evolving research indicating the importance of multiple-receptor blockade to the effectiveness of the SGA class. As the various neurotransmitter systems have been investigated in relation to the neuropsychopharmacology of schizophrenia, evidence is emerging that the SGAs, and olanzapine in particular, may improve different schizophrenia symptom domains through effects on 5-HT receptors, on multiple-receptor binding, on region-specific and more fleeting binding to dopamine receptors, on glutamate neurotransmission, and perhaps on neuropeptide neurotransmitters. In the following paragraphs, we discuss each of these specific ideas about olanzapine's mechanism of action in turn.

In clinical investigations with PET imaging, Kapur *et al.* (1998) showed that olanzapine at a wide range of dosages blocks a high percentage ([?] 95%) of 5-HT_{2A} receptors and blocks dopamine receptors in a dose-dependent fashion--crossing the putative antipsychotic blockade line at dosages commonly used to diminish psychotic symptoms of schizophrenia. This study indicated that olanzapine's primary mechanism was related to the blockade of dopamine receptors and additionally noted that olanzapine showed stronger affinity for 5-HT_{2A} receptors than for dopamine receptors at all dosage ranges.

A more compelling hypothesis regarding the mechanism of olanzapine's effects emerged from in vivo PET scanning work performed in a series of experiments at the University of Toronto and in Sweden. Results of the initial PET scanning studies of patients receiving clozapine indicated that atypical D_2 receptor binding was occurring (Farde and Nordstrom 1992; Farde *et al.* 1992; Kapur *et al.* 2000). The group subsequently found similar unusual D_2 receptor binding with quetiapine and, to some degree, olanzapine (Kapur *et al.* 1998). The authors proposed that the so-called atypical antipsychotic effect--successful treatment of psychotic symptoms with limited induction of movement disorder side effects--may be the result of a "fast-off" property of some SGAs, wherein the drug blocks the D_2 receptor but leaves it quickly, a receptor occupancy pattern that effectively decreases psychosis yet causes minimal interference to the body's own dopamine receptor activity. Thus, for olanzapine, this mechanism might help explain how the drug can exert strong therapeutic effects on schizophrenia symptoms yet cause few EPS at standard dosages. From a clinical viewpoint, it is important to note that at higher olanzapine dosages (30 mg/day), greater dopamine receptor blockade is seen, and movement disorder side effects such as akathisia are more likely to occur.

For more than 40 years, there has been substantial interest in the role of glutamate, an excitatory neurotransmitter, in the pathophysiology of schizophrenia (e.g., Moghaddam and Javitt 2012). Its inclusion in theories about the development of schizophrenia is supported by the psychotomimetic properties of glutamate antagonists such as phencyclidine and ketamine. These NMDA receptor antagonists induce a group of behaviors that often show closer parallels to schizophrenia than do those induced by dopamine sympathomimetic agents, in both mice and humans. Clinical trial evidence points to the potential usefulness of glutamatergic agonists (e.g., D-cycloserine) in treating schizophrenia (Kantrowitz *et al.* 2010). One way of examining the potential effectiveness of medication is to look at changes in deficits in *prepulse inhibition* (i.e., attenuation of the startle response), a measure of sensory motor gating that is diminished in patients with schizophrenia and can be similarly diminished pharmacologically through administration of phencyclidine (Dulawa and Geyer 1996). In a study of rats with isolation-induced disruption of prepulse inhibition, both quetiapine and olanzapine successfully reversed the prepulse inhibition deficit (Bakshi *et al.* 1998).

In summary, olanzapine works at least at the dopamine, 5-HT, and glutamate receptors. Current theories suggest that dopamine receptor-blocking capabilities are a necessary but not sufficient requirement for antipsychotic effectiveness. The other studied mechanisms, when taken in total, may be the factors leading to olanzapine's broad efficacy and side-effect profile.

Indications and Efficacy

Olanzapine initially received FDA approval for the treatment of psychotic disorders. Currently, it has multiple indications, including treatment of schizophrenia; acute treatment of manic or mixed states in bipolar disorder; and maintenance treatment of bipolar disorder, both as monotherapy and as an adjunct to mood stabilizer therapy. The OFC preparation has an FDA indication for bipolar depression and treatment-resistant depression. The olanzapine/samidorphan combination is also indicated for schizophrenia and bipolar I disorder (acute and maintenance treatment) in adults. Intramuscular olanzapine carries an indication for acute agitation in schizophrenia and bipolar mania. Olanzapine is approved for adults and for children ages 13-18 years.

In addition to the approved indications, olanzapine has been studied--and at times used with limited evidence--in several other illnesses. In this section, we present the evidence base supporting the use of olanzapine for its FDA-indicated uses as well as for off-label uses.

Approved Indications

Schizophrenia

As noted earlier, olanzapine was originally developed as a medication with potential for treating schizophrenia, mania, and anxiety. To gain FDA approval for the treatment of schizophrenia, olanzapine was tested in four pivotal studies to assess the compound for efficacy, safety, and dosage range. The earliest testing was an assessment of dosages of 5-30 mg/day following an initial starting dosage of 10 mg/day. Brief Psychiatric Rating Scale (BPRS) scores were reduced substantially, and EPS incidence was low (Baldwin and Montgomery 1995). These encouraging results led to further studies and pointed to a dosage range to be tested. Notably, the Schizophrenia Patient Outcomes Research Team study found that olanzapine was associated with significant metabolic risks and suggested that it should not be considered a first-line treatment for individuals experiencing their first episode of schizophrenia (Buchanan *et al.* 2010).

Efficacy studies. The first pivotal study compared two dosages of olanzapine (1 mg/day and 10 mg/day) with placebo in a large international sample. The 10 mg/day dosage was statistically significantly superior to placebo on objective rating scales (Beasley *et al.* 1996a). The second pivotal study was a dose-ranging comparison of olanzapine versus haloperidol and placebo, also in a large international sample. Three dosage ranges for olanzapine were included: 1) low (5 +- 2.5 mg/day), 2) medium (10 +- 2.5 mg/day), and 3) high (15 +- 2.5 mg/day). Haloperidol was dosed to 15 +- 2.5 mg/day. Olanzapine at the medium and high dosage ranges and haloperidol were associated with significant improvements compared with placebo (Beasley *et al.* 1996b). Beasley *et al.* (1997), using the same sample, further demonstrated that acute EPS were reported less frequently in all olanzapine dosage groups than in the haloperidol group. Tollefson and Sanger (1997) reanalyzed data from the first two studies and found that olanzapine had a direct therapeutic effect on negative symptoms that was not mediated by its effects on positive symptoms, EPS, or mood.

Another large international multicenter trial used a flexible dosing strategy to show olanzapine's clinical superiority to haloperidol on positive symptoms, negative symptoms, comorbid depression, EPS, and overall drug safety. In this study, patients were started on olanzapine or haloperidol at dosages ranging from 5 to 20 mg/day. Ultimately, patients received olanzapine 13.2 mg/day or haloperidol 11.8 mg/day (Tollefson *et al.* 1997).

The group of studies just described led to olanzapine's approval for psychosis (later changed to schizophrenia). Several other studies have confirmed olanzapine's efficacy in the treatment of schizophrenia. With its added benefit of low movement-disorder side effects, olanzapine has become an important addition to the armamentarium of the psychiatrist treating schizophrenia. Leucht *et al.* (1999) reported that olanzapine was statistically more effective than placebo (moderate effect) and more effective than haloperidol (small effect) on global schizophrenia symptomatology.

A large National Institute of Mental Health-funded investigation sought to compare the SGAs olanzapine, risperidone, quetiapine, and ziprasidone with perphenazine to understand the efficacy and side-effect profiles of newer versus older antipsychotic medications (Lieberman *et al.* 2005). This project, the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE), was designed to provide a double-blind yet reasonably naturalistic setting for clinicians to treat patients, using time to discontinuation for any reason as the primary outcome variable. Although olanzapine had the longest time to all-cause discontinuation of any medication in the trial, it also had the highest rate of discontinuation due to metabolic complications such as weight gain, whereas perphenazine had the highest rate of discontinuation due to EPS. Overall, however, the discontinuation rate was high for all medications, with nearly 75% of patients changing medications within the 18-month study duration. Much discussion and written commentary has ensued since the initial findings were published, including analyses of cost-effectiveness (Rosenheck *et al.* 2006), of the effects of antipsychotic medication on psychosocial functioning (Swartz *et al.* 2007), and of the impact of switching medications (Essock *et al.* 2006), as well as numerous editorials about the treatment implications of the study.

Schizophrenia is often not fully responsive to antipsychotic treatment. This places olanzapine in a difficult position in treatment algorithms because metabolic side effects limit its use in early psychosis, but its use is not supported in lieu of clozapine in refractory psychosis. Assessment of olanzapine in patients with treatment-refractory illness did not support its usefulness in a stringent nonresponder protocol (Conley *et al.* 1998). A second phase of the CATIE project examined the use of clozapine in patients with treatment-refractory illness and found, based on the time to discontinuation, that clozapine was a superior treatment for patients whose illness had not responded to other SGAs (McEvoy *et al.* 2006).

Although early research noted olanzapine's beneficial effects on negative symptoms and cognitive symptoms of schizophrenia, these effects were not as strong as the drug's effects on positive symptoms. In a flexible-dose comparison between risperidone and olanzapine in patients followed for 1 year, olanzapine-treated patients showed significantly greater improvement on Scale for the Assessment of Negative Symptoms (SANS) scores than did risperidone-treated patients (Alvarez *et al.* 2006). In contrast, a study by researchers from Eli Lilly followed patients taking either quetiapine or olanzapine for 6 months and found similar improvements on the SANS at study completion in both groups (Kinon *et al.* 2006). In a meta-analysis of 50 studies of SGAs (Komossa *et al.* 2010), no difference in short-, medium-, or long-term improvement of negative symptoms (as measured by Positive and Negative Syndrome Scale [PANSS] negative, BPRS negative, and/or SANS total scores) was found between olanzapine and the other medications, which included amisulpride, clozapine (1 of 12 studies found clozapine to be superior as measured by SANS total scores), quetiapine, and ziprasidone (1 of 2 studies found olanzapine to be superior on PANSS negative scores, but overall no difference was found). An additional meta-analysis of 21 randomized controlled trials (RCTs) (*n* = 3,451 subjects) concluded similarly that olanzapine did not show benefit over placebo on negative symptoms (Krause *et al.* 2018).

Cognitive functioning is the most important indicator of schizophrenia prognosis (Green 2006). In a 1-year comparison of olanzapine with risperidone, both groups showed modest benefits on a cognitive function battery (Gurpegui *et al.* 2007). In a study conducted over a 1-year period by Eli Lilly researchers in Spain, olanzapine-treated patients showed greater benefit in social functioning than did risperidone-treated patients, as assessed by scores on the Social Functioning Scale. The greatest difference was in occupation/employment, but improvements were also seen on measures of independence, social engagement, and recreation (Ciudad *et al.* 2006).

In an 8-week double-blind, placebo-controlled study, the LAI formulation of olanzapine showed a statistically significant separation from placebo (as measured by decreases in PANSS total scores) that was evident by day 7 (Lauriello *et al.* 2008). Another study of olanzapine LAI that involved a longer period of treatment--24 weeks--found that a high percentage of subjects remained free of psychotic exacerbation (Kane *et al.* 2010).

Studies have investigated olanzapine's efficacy in the treatment of schizophrenia spectrum and other psychotic disorders in adolescents. An important caveat is that these studies are for those who have experienced psychotic symptoms beyond the threshold for diagnosis. Olanzapine is not indicated for use in those considered at risk for development of psychosis (McGlashan *et al.* 2006). In a systematic review of the literature on antipsychotic use in children, SGAs were shown to be beneficial overall in improving psychotic symptoms (Jensen *et al.* 2007). Olanzapine's safety profile in adolescents is similar to its profile in adults, although its adverse effects on weight and prolactin are more significant in young people (Kryzhanovskaya *et al.* 2009). A double-blind, flexible-dose study demonstrated comparable efficacy for risperidone, olanzapine, and haloperidol in young people with psychosis (Sikich *et al.* 2004). A similar trial of olanzapine, risperidone, and quetiapine in early psychosis found equivalent rates of discontinuation for the three drugs over a 52-week period, with olanzapine and risperidone showing slightly greater reductions on PANSS positive scores compared with quetiapine (McEvoy *et al.* 2007). In late 2009, olanzapine received FDA approval for the treatment of schizophrenia in teenagers, but with the recommendation that clinicians first consider other agents given concerns about metabolic

consequences (for further discussion, see "Side Effects and Toxicology" later in this chapter).

At the other end of the age spectrum, olanzapine has been investigated in the treatment of psychotic disorders in elderly persons. Olanzapine, like all antipsychotic medications, carries an FDA black box warning regarding an increased risk of stroke associated with its use in elderly individuals with dementia-related psychosis. (Use of olanzapine in dementia is discussed in greater detail later in this chapter; see "Dementia-Related Agitation and Psychosis.") A study of olanzapine versus haloperidol in a group of older patients with chronic schizophrenia found a statistical advantage for olanzapine (Krause *et al.* 2018). In a study of olanzapine in 94 acutely ill inpatients age 65 years or older, some with psychosis, Hwang *et al.* (2003) reported mean reductions from baseline of greater than 50% on BPRS scores, thus illustrating olanzapine's usefulness in treating a broad range of psychotic symptoms in older patients. As with any treatment used in elderly persons, special care must be taken to avoid cardiovascular complications as well as risks associated with olanzapine's anticholinergic properties. With olanzapine, orthostatic hypotension, oversedation, and thus the risk of falls must be factored into the dosing decision (Gareri *et al.* 2006).

Treatment approaches. Early studies of olanzapine assessed dosages ranging from 5 to 30 mg/day. When olanzapine was initially released, it was recommended that the medication be started at a dosage of 10 mg/day, often given as a bedtime dose. Although the FDA-approved maximum dosage is 20 mg/day, it is not uncommon for olanzapine to be used off-label at dosages up to 40 mg/day, particularly in acute settings. Looking at the dose-response curves, the ED95, corresponding to the point on the curve that shows a 95% response rate, was 15.1 mg. The dose-response curve had not flattened fully by that dose, however, meaning that higher doses may in fact also be beneficial, particularly in certain individuals (Leucht *et al.* 2020). In the flexible-dosing segment of the CATIE, in which the available dosages were 7.5, 15.0, 22.5, and 30.0 mg/day, the average dosage was 20.1 mg/day (Lieberman *et al.* 2005). Because some patients appear to have an inadequate response to olanzapine at the recommended dosages, clinicians have assessed its usefulness at dosages above the recommended 20 mg/day. Many hospital clinicians employ a loading strategy with olanzapine, particularly in young, otherwise healthy patients presenting with acute agitation, using dosages up to 40 mg/day for the first 2 days and gradually decreasing to a target dosage of 20-30 mg/day (Brooks *et al.* 2008). Although sedation and hypotension must be watched for in any individual patient, increased rates of those side effects were not seen in a study comparing the loading-dose strategy with 10 mg/day dosing (Baker *et al.* 2003). Conversely, patients early in their course of psychosis, particularly if not presenting with acute agitation, may benefit from lower dosages and a more gradual titration if olanzapine is to be used (Keating *et al.* 2021).

Typically, agitated patients are best treated with the rapid-dissolving preparation of olanzapine. The rapid-dissolving tablet formulation is preferable to the conventional pill in the acute setting, particularly when some sedation is also needed, given its faster onset of action and the decreased risk of "cheeking" the medication. When patients are severely agitated, use of injectable olanzapine may also be necessary. The intramuscular preparation has a rapid onset of action similar to that of dissolvable tablets and a certainty of delivery that is imperative in an emergency. It has been

shown to be superior to placebo at dosages of 10 mg/day and as effective as haloperidol, with significantly fewer side effects (Breier *et al.* 2002). Case reports caution against the use of olanzapine in conjunction with intramuscular lorazepam because of the risk of hypotension, although recent research has called that warning into question (Williams 2018).

For patients who require long-term treatment, LAI olanzapine can be used on a biweekly or once-monthly administration schedule. Because of concerns regarding cases of delirium and even coma reported in early studies, individuals receiving LAI olanzapine must be observed for 3 hours after the injection. This monitoring requirement has significantly limited the use of the LAI form. For patients taking an oral dosage of 10-15 mg/day, olanzapine pamoate can be administered monthly (150/300 mg every 2/4 weeks for an oral dosage of 10 mg/day, and 210/405 mg every 2/4 weeks for an oral dosage of 15 mg/day). For individuals switching from an oral dosage of 20 mg/day, olanzapine pamoate should be administered at 300 mg every 2 weeks (Eli Lilly 2021).

Bipolar Disorder and Treatment-Resistant Depression

Before the introduction of SGA medications, traditional antipsychotic medications were well known to be useful in the treatment of mania. Findings from a study assessing the effects of olanzapine versus haloperidol on symptoms of schizoaffective disorder provided a rationale for studying olanzapine in bipolar disorder; in this study, patients who received olanzapine showed superior outcomes on many, but not all, measures compared with patients who received haloperidol (Tran *et al.* 1999).

The first controlled study of olanzapine in bipolar disorder was a 21-day comparison of olanzapine with placebo (Tohen *et al.* 1999). Significantly greater improvement in manic symptoms (as assessed by mean change from baseline to endpoint in Young Mania Rating Scale [YMRS] total score) was observed for patients taking olanzapine compared with those taking placebo. No difference was seen in the outcomes for depression. In this study, EPS were not more frequent in patients taking olanzapine than in those taking placebo (Tohen *et al.* 1999). These findings were confirmed in a second pivotal study that also showed an advantage for olanzapine over placebo (Tohen *et al.* 2000). An open-label follow-up (49 weeks) added valuable information, especially noting that decreases in YMRS scores continued. For the longer term, depression scores also improved. Importantly, for the patients who were exposed to olanzapine at a mean dosage of approximately 14 mg/day, no cases of tardive dyskinesia occurred (Sanger *et al.* 2001).

A question of practical interest is how olanzapine compares with conventional mood stabilizers. In a double-blind trial conducted by Eli Lilly, olanzapine was compared with lithium in the maintenance treatment of bipolar disorder (Tohen *et al.* 2005). Patients were stabilized on a combination of lithium and olanzapine and then randomly assigned to receive one or the other for 52 weeks. In the noninferiority analysis, olanzapine was shown to be as effective as lithium in preventing depression relapse, and the patients given olanzapine had lower rates of mixed or manic symptom relapse over the 52-week follow-up than did those given lithium. Weight gain was higher in the olanzapine group (Tohen *et al.* 2005). Further studies similarly confirmed the equivalent efficacy of olanzapine and divalproex (Tohen *et al.* 2002). This line of research led to FDA approval of olanzapine for the treatment of manic symptoms.

The mean dosage used in olanzapine monotherapy for mania is similar to that used in schizophrenia: 13 mg/day. For acute mania in agitated bipolar patients, intramuscular olanzapine has been shown to be effective (Meehan *et al.* 2001).

The treatment of bipolar depression is often complex. Monotherapy with antidepressants is associated with an increased risk of switching into mania. The OFC is FDA approved for treatment of bipolar depression. In an

8-week double-blind trial conducted by Eli Lilly, OFC was compared against olanzapine monotherapy and placebo in patients with bipolar I disorder in a depressed phase. Although both active treatments were more effective than placebo, OFC was significantly more effective than olanzapine in treating depressive symptoms. By the fourth week of the study, OFC-treated patients showed greater improvement in mood than did olanzapine-treated patients (Tohen *et al.* 2003). Subjects' health-related quality of life also improved (Shi *et al.* 2004). Rates of treatment-emergent mania with OFC were low and did not significantly differ from rates with placebo or olanzapine monotherapy (Amsterdam and Shults 2005; Tohen *et al.* 2003). Recent meta-analyses have shown olanzapine to have a durable benefit for bipolar depression (Bahji *et al.* 2020); however, given the risks associated with olanzapine, the International Society for Bipolar Disorders designates OFC as a second-line agent in its most recent guidelines (Yatham *et al.* 2018).

In adolescents with bipolar I disorder, Tohen *et al.* (2007) reported significantly greater improvement in mania ratings with olanzapine than with placebo. A study conducted by Eli Lilly demonstrated that OFC was superior to placebo in bipolar adolescents in a double-blind RCT (Detke *et al.* 2015). Side effects were similar to those in adults, including changes in glucose and lipids. Both olanzapine and OFC have been FDA approved for bipolar depression in adolescents.

OFC has been studied and FDA approved for use in treatment-refractory major depressive disorder. Thase *et al.* (2007) conducted a study comparing OFC with olanzapine or fluoxetine monotherapy in patients who had not shown adequate response to at least two prior trials of antidepressants. In the pooled analysis (Thase *et al.* 2007), OFC produced greater improvement than olanzapine monotherapy or fluoxetine monotherapy (as assessed by scores on the Montgomery-Asberg Depression Rating Scale [(MADRS]). In a double-blind trial sponsored by Eli Lilly, olanzapine, fluoxetine, OFC, and venlafaxine showed similar rates of efficacy (Corya *et al.* 2006).

Off-Label Uses

Dementia-Related Agitation and Psychosis

Olanzapine does not have an FDA-approved indication for treating elderly patients with dementia and carries a black box warning for use in this population due to increased risk of death, primarily from cardiovascular and infectious complications (U.S. Food and Drug Administration 2011). Professional organizations, including the American Medical Directors Association (2012) and the American Geriatrics Society, recommend against the use of antipsychotics as a first choice to treat behavioral and psychological symptoms of dementia (Rabins *et al.* 2007). However, when agitation is of sufficient severity, and if psychosis is at the root of the agitation--with appropriate discussion of risks and benefits--olanzapine may be a reasonable option (Duong *et al.* 2015).

A large placebo-controlled trial of olanzapine in patients with Alzheimer's disease showed that lower dosages of olanzapine (5-10 mg/day) were significantly better than placebo in treating target symptoms of agitation, hallucinations, and delusions (Street *et al.* 2000). Other trials have since replicated these findings with similar doses (De Deyn *et al.* 2004). A recent comparative meta-analysis was unable to differentiate between the risks and benefits for olanzapine and those for aripiprazole, quetiapine, or risperidone, although olanzapine and risperidone did show increased risk for stroke compared with placebo. Olanzapine also did not differ from placebo on any measures of effectiveness, including the Neuropsychiatric Inventory (NPI), which measures dementia-related behavioral symptoms (Yunusa *et al.* 2019).

Several studies have examined olanzapine in the treatment of dementia without agitation (Brooks and Hoblyn 2007). A placebo-controlled multicenter trial conducted by researchers at Eli Lilly evaluated olanzapine at low fixed dosages (1.0, 2.5, 5.0, and 7.5 mg/day) for treating dementia-related psychosis (De Deyn *et al.* 2004). Although olanzapine did not separate from placebo on the primary outcome measure, the Hallucinations and Delusions items of the NPI Nursing Home edition, improvements were seen in each dosage group studied. All patients who received dosages of 2.5 mg/day or higher were initially started on 2.5 mg/day, with the dosage titrated upward by 2.5 mg/week (as indicated based on assigned study group). There were significant differences from placebo in the acute phase of the study, suggesting that 2.5 mg/day could be an effective starting dosage in acute settings. Regarding secondary outcomes, the most significant improvement was seen with the highest olanzapine dosage (7.5 mg/day), suggesting that up-titrating dosages may be beneficial for some individuals if tolerated. Because no higher dosages were studied, it is unclear whether further increases would lead to greater efficacy (De Deyn *et al.* 2004).

Enhancement of brain levels of acetylcholine has been the focus of treatments aimed at slowing the rate of cognitive deterioration among individuals with dementia. The clinical use of cholinesterase inhibitors is based on that rationale. Olanzapine may have beneficial effects on the regulation of cholinergic and serotonergic neurons that mediate acetylcholine release in the prefrontal cortex. However, in a double-blind study conducted by researchers at Eli Lilly, olanzapine was shown to worsen cognitive functioning, as assessed on the Alzheimer's Disease Assessment Scale for Cognition. Also, there was no statistical difference between the olanzapine and placebo groups in scores on the Clinician's Interview-Based Impression of Change scale (Kennedy *et al.* 2005). Patients in the olanzapine group also showed cognitive worsening on the Mini-Mental State Examination (MMSE). Previous studies found little or no benefit for cognition from olanzapine treatment in non-agitated patients with dementia (De Deyn *et al.* 2004; Street *et al.* 2000).

The CATIE study, which had an Alzheimer's disease component (Schneider *et al.* 2006b; Vigen *et al.* 2011), also compared olanzapine, risperidone, and quetiapine with placebo in the treatment of psychosis and agitation in outpatients. Patients were included if they had psychotic symptoms and resided either in an assisted-living facility or at home. They were excluded if they needed skilled nursing, had primary psychotic disorders, or had previously received cholinesterase inhibitors or antidepressants. As in the schizophrenia portion of CATIE, the primary outcome variable was time to discontinuation. There was no difference among the groups, and no benefit on the Alzheimer's Disease Cooperative Study-Clinical Global Impression of

Change. The average time to discontinuation ranged from 5 to 8 weeks among the treatments. Discontinuation due to lack of efficacy occurred sooner for patients receiving placebo or quetiapine than for those receiving risperidone or olanzapine. Side effects such as parkinsonism, sedation, and increased BMI occurred more frequently with the study medications than with placebo (Schneider *et al.* 2006b; Vigen *et al.* 2011).

Overall, the evidence supporting the effectiveness of SGAs in the treatment of dementia is weak. Olanzapine should not be the first choice when managing dementia-related agitation. Physicians must remember the risks of worsened cognitive function and metabolic dysfunction when prescribing this medication. Current consensus and guidelines agree that evidence for treatment of dementia-related agitation and psychosis with olanzapine is insufficient and recommend against its routine use (Frederiksen *et al.* 2020). Nonetheless, behavioral consequences and patient safety may sometimes require more aggressive treatment, and antipsychotic medication may be warranted. Olanzapine is considered an intermediate-risk antipsychotic in this population (Kales *et al.* 2012). Ultimately, a painstaking evaluation of the risk-benefit ratio for antipsychotic medication use must precede any decision to prescribe these agents in both the short and long terms. Further studies are needed, however, regarding the use of SGA medications in this population (Schneider *et al.* 2006a).

Borderline Personality Disorder

Borderline personality disorder (BPD) is a severe disorder with a U.S.A. point prevalence of 1.6% and a lifetime prevalence of 5.9% (Lenzenweger *et al.* 2007). Earlier studies indicated that low dosages of traditional antipsychotic medications might be useful for symptoms in the psychosis spectrum and overall symptoms of BPD. On the basis of this idea, Schulz *et al.* (1999) conducted an open-label study and found that olanzapine led to substantial improvement in psychoticism, depression, interpersonal sensitivity, and anger (as measured by Hopkins Symptom Checklist-90 ratings), as well as improvement on objective measures of impulsivity and aggression. Of the 11 women enrolled, 9 (82%) completed the study. The trial allowed for early flexible dosing, and the subjects ended their 8 weeks taking an average dose of 7.5 mg/day at bedtime. Zanarini and Frankenburg

(2001) extended this trial and demonstrated olanzapine's (5 mg/day) superiority to placebo over a 26-week study period.

In a study comparing olanzapine, fluoxetine, and a combination of both drugs in women with BPD, olanzapine monotherapy was found to be more effective (as assessed with the MADRS) than either fluoxetine or the olanzapine/fluoxetine combination in treating the depressive symptoms of the disorder. Additionally, olanzapine was superior to fluoxetine in treating symptoms of impulsivity and aggression, as measured by the Overt Aggression Scale. Weight gain was more frequent among olanzapine-treated patients than among patients receiving either of the other two compounds (Zanarini *et al.* 2004).

Two large placebo-controlled studies evaluating olanzapine in BPD yielded mixed results. Schulz *et al.* (2008) reported no significant advantage for olanzapine over placebo in a flexible-dosing design, whereas Zanarini *et al.* (2011) noted a statistical advantage for higher-dosage olanzapine in a fixed-dose trial comparing low-dosage olanzapine, higher-dosage olanzapine, and placebo for 12 weeks. In an open-label 12-week extension phase of the same study, Zanarini *et al.* (2012) found that patients

treated with olanzapine in the initial study maintained the modest improvements in their symptoms. Patients treated with placebo in the initial 12 weeks who were crossed over to olanzapine in the extension phase achieved a level of symptom relief similar to those who had started with olanzapine. These mixed results demonstrate the controversies of using antipsychotic medications in BPD.

Dialectical behavior therapy (DBT) is the mainstay of treatment for BPD. In a double-blind, placebo-controlled trial, olanzapine was studied as an adjunctive agent in patients receiving DBT. Impulsive and aggressive behaviors were found to be lower in the group that received olanzapine than in the placebo group. The average olanzapine dosage in the trial was 8.8 mg/day. Statistically significantly greater increases in weight gain and dyslipidemia were observed in the olanzapine group compared with the placebo group (Soler *et al.* 2005). A similar trial also demonstrated significant improvement in irritability, aggression, depression, and self-inflicted injury for patients in the adjunctive olanzapine group (Linehan *et al.* 2008). It is possible that olanzapine, particularly in conjunction with DBT, may be helpful for treating impulsivity, aggression, and depressive symptoms in BPD; attention to side effects and risks is warranted and ultimately limits use of olanzapine in this population.

Anorexia Nervosa

Anorexia nervosa (AN) is a severe psychiatric illness that carries the highest mortality rate among mental disorders, with a lifetime prevalence between 0.5% and 3% (Campbell and Peebles 2014). Severe restriction of food intake and consequent low weight are primary features of the disorder. Additionally, patients may have psychotic-like disturbances in self-perceived body size or shape, as well as unusual ideas about food and metabolism. Olanzapine was proposed as a treatment adjuvant for this population. Current knowledge largely comes from pilot studies and case series, with some data emerging from small, controlled trials.

In an open-label trial, 17 patients hospitalized for AN were given olanzapine in addition to cognitive-behavioral therapy (CBT) and DBT. Olanzapine's initial dosage of 1.25-5.00 mg/day was titrated upward as needed, balancing efficacy against side effects. Patients showed improvement in weight and Beck Depression Inventory and Spielberger State-Trait Anxiety Inventory scores, but the lack of a control group limited the validity of these results (Barbarich *et al.* 2004). A randomized trial in which 15 women with AN were assigned to either olanzapine or chlorpromazine in a balanced block design found that olanzapine reduced anorexic ruminations (as measured by the impaired control over mental activities subscale of the Padua Inventory). There was no difference in weight gain between the two groups. However, this study was limited by its nonblinded design (Mondraty *et al.* 2005). A case series evaluating low-dosage olanzapine treatment in 13 adolescent girls with restricting-type AN reported weight increase and lower hyperactivity in the 7 girls who responded to olanzapine (response was defined as improvement of at least 50% on the Eating Attitudes Test-26) (Leggero *et al.* 2010).

Results of double-blind RCTs are mixed. In a 10-week trial of 34 women with AN, Bissada *et al.* (2008) found significant increases in weight and reductions in obsessive symptoms among those treated with olanzapine. Similarly, in an 8-week study of 23 outpatient women with AN, end-of-treatment BMI was greater among women receiving olanzapine than those receiving placebo. Psychological symptoms improved

equally in both groups (Attia *et al.* 2011). However, a trial of olanzapine versus placebo in 20 adolescent girls with AN found no differences in median body weight at either week 5 or week 10. The two groups showed similar improvements in eating attitudes, psychological functioning, and resting energy expenditure (Kafantaris *et al.* 2011).

Most recently, in a double-blind RCT, 152 adult outpatients diagnosed with AN were randomly assigned to either olanzapine or placebo treatment over 16 weeks. Weight gain and obsessive traits were the primary outcomes of this study. Obsession was rated by the Yale-Brown Obsessive Compulsive Scale (Y-BOCS). Patients in the olanzapine treatment group had statistically significantly greater gains in weight but no differences in psychological symptoms compared with the placebo group (Attia *et al.* 2019).

Given that weight gain is a prominent side effect of olanzapine, studies are examining the mechanisms underlying this effect and the possibility that olanzapine might be useful as a weight-gain agent. In a double-blind, placebo-controlled trial, Brambilla *et al.* (2007) investigated whether olanzapine might induce weight gain through modulation of ghrelin and leptin (hormones associated with satiety). Patients with AN received olanzapine or placebo with CBT, and their levels of ghrelin and leptin were assessed over 3 months. Patients in both the olanzapine and placebo groups had increased weight, but there was no statistical difference between the groups regarding weight gained or levels of leptin or ghrelin, which remained unchanged over the course of the study.

The role of olanzapine as an augmentation to psychotherapy in AN is limited at best. Most high-quality studies did not find psychological or physical improvement for patients treated with the drug. However, there may be a limited role for olanzapine in patients for whom timely weight gain is medically imperative and urgent. Since the trials thus far have been small and the results mixed, further research is required to clarify this matter.

Posttraumatic Stress Disorder

PTSD is characterized by disproportionate and disturbing symptoms of fear persisting for longer than 1 month following a severe trauma. In some cases, psychosis can occur, leading to intense feelings of horror and helplessness. This phenomenon led investigators to consider a potential role for olanzapine in the treatment of PTSD, although available data are still limited.

In a double-blind, placebo-controlled augmentation trial of olanzapine in 19 patients with PTSD who were minimally responsive to 12 weeks of selective serotonin reuptake inhibitor (SSRI) treatment, olanzapine produced limited symptomatic improvements compared with placebo on measures of PTSD, depression, and sleep. However, clinician-rated overall clinical response rates did not differ between the groups. Patients receiving olanzapine had an average weight gain of 13 lb (Stein *et al.* 2002).

An open-label study compared olanzapine versus fluphenazine as monotherapy for 6 weeks in male patients with combat-related PTSD and psychosis. Olanzapine was significantly more efficacious in reducing symptom scores on the PANSS (negative, general, psychopathology subscale, supplementary items), Watson's PTSD subscales (avoidance, increased arousal), and a variety of global impression scales (Clinical Global Impression Severity and Improvement scales and Patient Global Impression Improvement [PGI-I] scale) at 3 and 6 weeks. The two medications produced similar improvements on PANSS positive and Watson's trauma reexperiencing subscale scores. An additional 3 weeks of treatment did not increase symptom improvements for either drug (Pivac *et al.* 2004).

A small double-blind RCT studied patients with non-combat-related PTSD. Patients in this study who received olanzapine demonstrated significantly greater improvement on the Clinician-Administrated PTSD

Scale over 8 weeks of treatment compared with those who received placebo (Carey *et al.* 2012). This was the most recent trial looking into this association, and no ongoing trials currently are registered on clinicaltrials.gov. Hence, evidence supporting the use of olanzapine in PTSD is weak at best.

Obsessive-Compulsive Disorder

OCD is characterized by recurrent, unwanted, and anxiety-inducing obsessive thoughts and the repetitive behaviors compulsively performed as an attempt to ease those thoughts. At times, obsessions are so disconnected from reality that they resemble psychosis. A few double-blind, placebo-controlled clinical trials have examined olanzapine's potential efficacy in augmentation of traditional SSRI treatment of OCD.

One trial enrolled 26 patients who had not responded to traditional SSRI therapy. Patients received olanzapine or placebo augmentation for 6 weeks and were assessed biweekly with the Y-BOCS. Six (46%) of the 13 olanzapine-treated patients showed clinical response (defined as a 25% or greater reduction on Y-BOCS scores), versus none in the placebo group (Bystritsky *et al.* 2004). In a second trial, poor responders to fluoxetine received an additional 6 weeks of either olanzapine or placebo augmentation. Both groups improved, but there were no differences between groups in the extent or timing of improvement as measured by Y-BOCS scores (Shapira *et al.* 2004).

More recent studies suggest that olanzapine is effective in only a limited set of patients with OCD, mainly those with hoarding or symmetry-based symptoms. Available data do not support olanzapine as a first-line drug for OCD (Matsunaga *et al.* 2009). Given the mixed results and small sample sizes of the existing studies, further research is needed to establish possible benefits of olanzapine augmentation for OCD. Currently, no registered ongoing clinical trials are looking into this association.

Delirium

Delirium is a neuropsychiatric syndrome characterized by acute and fluctuating changes in mental status, circadian rhythm, and cognition. It is generally attributed to underlying medical conditions, such as infections, hydroelectrolytic disorders, and CNS perturbations. Delirium is a marker of poor clinical outcomes because it is associated with cognitive decline, prolonged hospitalization, institutionalization, personal and caregiver suffering, and a higher risk of death (Inouye *et al.* 2014). With an estimated prevalence of 20% in hospitalized adults, 50% in mechanically ventilated patients, and up to 70% in inpatient palliative care patients (Gibb *et al.* 2020), there is high interest in the treatment of this condition. Several RCTs and open trials have studied the role of olanzapine as an adjuvant in the management of delirium.

Larsen *et al.* (2010) compared the efficacy of 10 mg of orally disintegrating olanzapine versus placebo in a prophylaxis trial. Their population consisted of 400 elderly persons ages 65 years and older undergoing elective knee or hip replacement surgeries. A 5-mg pill was given just before and just after surgery. The olanzapine group had a lower rate of delirium, in both types of surgery. However, for those patients who developed the disorder while taking olanzapine, it lasted longer and was more severe.

Yoon *et al.* (2013) compared haloperidol, risperidone, olanzapine, and quetiapine in the treatment of delirium in an inpatient setting. Outcomes were measured with the Korean version of the Delirium Rating Scale-Revised 98 (DRS-K) and the MMSE. A total of 80 patients were evenly distributed among the four groups; there were no differences in baseline DRS-K and MMSE scores. All groups had similar rates of improvement, and there were no significant differences in subscale scores. The response rate was lower in individuals older than 75 years, regardless of the group. Also, there were no differences in side-effect profiles. Grover *et al.* (2011) previously performed a similar comparison of olanzapine, risperidone, and olanzapine and also did not find any differences among the groups.

Jain *et al.* (2017) performed an open-label RCT with 100 patients admitted to different medical wards. Delirium was assessed with the Confusion Assessment Method Scale. Patients were given haloperidol (1-4 mg/day) or olanzapine (2.5-10 mg/day). Outcomes included improvement in symptom scores on the Memorial Delirium Assessment Scale and rate of extrapyramidal side effects on the Simpson Angus Scale. Both groups had similar symptomatic improvements, with no differences in side effect occurrence. Lin *et al.* (2008) previously performed a similar comparison of haloperidol and olanzapine and found no differences between the groups.

As of now, data support the role of antipsychotics as an adjuvant in the management of delirium. We highlight that investigating and treating the underlying cause should always be the priority. There seem to be no differences between olanzapine and other commonly used antipsychotics.

Nausea and Vomiting

Guidelines established by the American Society of Clinical Oncology (ASCO) (Hesketh *et al.* 2017) and the National Comprehensive Cancer Network (2018) already recommend olanzapine as an adjuvant in the management of chemotherapy-induced nausea. In this context, patients benefit from the quadruple combination of olanzapine 10 mg, a 5-HT_3 receptor antagonist, a neurokinin$_1$ (NK_1) receptor antagonist, and dexamethasone. Smaller doses could be used for patients older than 75 years to reduce the age-related risk of sedation. Hashimoto *et al.* (2020) conducted a multicenter double-blind RCT to evaluate the efficacy of olanzapine 5 mg added to triplet-combination antiemetic therapy (i.e., aprepitant, palonosetron, and dexamethasone) as a standard of treatment against highly emetogenic chemotherapy agents.

In the past decade, several other clinical trials investigated the efficacy of olanzapine for chemotherapy-induced nausea. Navari *et al.* (2011, 2016, 2020), Tienchaiananda *et al.* (2019), Clemmons *et al.* (2018), Babu *et al.* (2016), Wang *et al.* (2015), Mizukami *et al.* (2014), and L. Tan *et al.* (2009) conducted similarly structured trials that support current guidelines. In all studies, olanzapine-treated patients had greater reductions in nausea and emesis when compared with placebo. Additionally, with results similar to those of Hashimoto *et al.* (2020), all studies that looked at olanzapine as adjunctive therapy also favored the quadruple combination strategy, with dosages varying from 5 mg to 10 mg/day.

The role of olanzapine in the treatment of non-oncological nausea and vomiting has not been studied, and therefore, no other recommendations can be made at this point.

Side Effects and Toxicology

Neurological and Extrapyramidal Adverse Effects

Adverse effects of olanzapine reported in clinical use are consistent with findings in preclinical studies, which predicted few neurological effects. In Phase II and III clinical trials, olanzapine-treated patients generally showed an improvement in EPS from baseline, reflecting the fact that most of the subjects had previously taken first-generation antipsychotics. In a large multinational comparison study (Tollefson *et al.* 1997), olanzapine produced fewer treatment-emergent neurological adverse effects than haloperidol, including parkinsonism (14% vs. 38%) and akathisia (12% vs. 40%). In a comprehensive meta-analysis, the relative risk (RR) of EPS for olanzapine was 0.39 compared with haloperidol (Leucht *et al.* 2009).

Antiparkinsonian medication is sometimes required when patients are treated with olanzapine, although the need for such medication is generally lower with olanzapine than with antipsychotics having greater potency at the D_2 receptor. In one study (Volavka *et al.* 2002), antiparkinsonian agents were prescribed to 13% of both clozapine-treated and olanzapine-treated subjects, compared with 32% of risperidone-treated patients. In a meta-analysis of RCTs, Komossa *et al.* (2010) found that olanzapine incurred a modestly higher risk of EPS (as measured by use of antiparkinsonian medication) compared with quetiapine (RR, 2.05) but a lower EPS risk compared with risperidone (RR, 0.78) and ziprasidone (RR, 0.70).

Evidence now exists for phenotypic variation in the risk of EPS among olanzapine-treated patients. A meta-analysis of 4,831 subjects compared the incidence of olanzapine-induced EPS in patients with schizophrenia versus patients with bipolar disorder. Parkinsonism was significantly higher among schizophrenia patients (13.9% vs. 3.1%), and this difference remained significant after adjustment for gender. There were no differences between groups on measures of akathisia or use of antiparkinsonian medication (Moteshafi *et al.* 2012).

The reduction of EPS is predictive of decreased risk of tardive dyskinesia, the most problematic of the common adverse effects of classic antipsychotics. Accumulated experience with SGAs indicates that tardive dyskinesia is 10-to 15-fold less common with these agents than with conventional agents, with an annual rate of 0.52% in olanzapine-treated patients compared with 7.45% in haloperidol-treated patients, based on pooled data from long-term comparison trials (Beasley *et al.* 1999). Miller *et al.* (2008) examined data from the previously described CATIE study; after excluding subjects who met criteria for tardive dyskinesia at baseline, they found no difference in incidence of tardive dyskinesia over 1 year between patients treated with olanzapine and patients treated with any other antipsychotic (perphenazine, quetiapine, risperidone, or ziprasidone).

Weight Gain and Other Metabolic Effects

Weight gain and associated dyslipidemia are among the most significant major adverse effects found during treatment with olanzapine. Weight gain is a serious concern because persons with schizophrenia are more likely than the general population to be obese, and weight gain may contribute to nonadherence to antipsychotic treatment, leading to increased risk for relapse. With the reduced risk of neurological side effects attached to SGAs, metabolic effects have emerged as a major risk for patients and a focus of consideration for clinicians.

Recent studies have attempted to find the cause of metabolic dysregulation associated with antipsychotic drugs. Aslanoglou *et al.* (2021) demonstrated that human and mouse pancreatic a- and b-cells express the catecholamine biosynthetic and signaling machinery and that a-cells synthesize dopamine de novo. This locally produced pancreatic dopamine signals via both a- and b-cell adrenergic and dopaminergic receptors with different affinities to regulate glucagon and insulin release. The investigators additionally found that dopamine functions as a biased agonist at a_{2A}-adrenergic receptors, preferentially signaling via the canonical G protein-mediated pathway. This ability of dopamine to signal differently on dopaminergic receptors versus adrenergic receptors may be critical for fine-tuning the regulation of blood sugar, which is essential for life. Aslanoglou *et al.* (2021) also showed that pharmacological blockade of D_2-like receptors in human islets with antipsychotic drugs significantly raises insulin and glucagon release. These findings provide new mechanisms to explain how antipsychotics act directly on islet a- and b-cell targets to produce metabolic disturbances (Aslanoglou *et al.* 2021).

The relative degree of weight gain associated with 18 antipsychotics was studied in a comprehensive meta-analysis by Pillinger *et al.* (2020). With a combined total of nearly 26,000 research subjects in 100 clinical trials (median duration 6 weeks), they replicated the classic work of Allison *et al.* (1999) showing that olanzapine and clozapine were the most likely antipsychotics to cause weight gain. These findings were also seen in long-term follow-up data (Kishimoto *et al.* 2019).

The treatment of olanzapine-induced metabolic dysfunction mirrors the treatments offered for weight gain or insulin resistance/diabetes in general. Lifestyle interventions should be the first line, with exercise (three times per week for 30 minutes to start) and a balanced, healthy diet focusing on whole grains, leafy green vegetables, and lean proteins (Vancampfort *et al.* 2019). Beyond that, there is a role for medication. Most well studied has been metformin, an agent known to decrease hepatic glucose output. Although not typically a weight-loss agent, metformin has been used both for its normoglycemic properties and to prevent or treat weight gain associated with olanzapine use. Investigators from the Use of Metformin in the Treatment of Antipsychotic-Induced Weight Gain in Schizophrenia Study randomly assigned 148 clinically stable overweight outpatients with schizophrenia or schizoaffective disorder to up to 2,000 mg of metformin or placebo daily (Jarskog *et al.* 2013). Patients were taking either one or two of any of the FDA-approved antipsychotic medications. All patients received weekly diet and exercise counseling. After 16 weeks, patients taking metformin had lost significantly more weight than those taking placebo (6.6 lb vs. 2.2 lb). The metformin group also showed significant reductions in triglyceride levels ([?] 7.0 mg/dL vs. + 13.2 mg/dL) and modest reductions in hemoglobin A1C, a measure of elevated blood glucose ([?] 0.06% vs. + 0.011%), with a time x treatment interaction, suggesting that the benefits of metformin increase with time. There were no significant differences in fasting glucose or insulin levels (Jarskog *et al.* 2013). More recently, glucagon-like peptide 1 (GLP-1) agonists have begun to show promise in countering the weight-gain effects of olanzapine, with more studies ongoing and newer GLP-1 agonists in development (Siskind *et al.* 2019). Other drugs associated with weight loss, including topiramate and a bupropion/naltrexone combination, have either failed to show efficacy or are limited by intolerable side effects in sufficient numbers to limit their utility.

In a double-blind, placebo-controlled trial in adolescents who had gained weight after 1 year of treatment with an SGA (olanzapine, risperidone, or quetiapine), the addition of metformin resulted in statistical reductions in waist circumference and BMI and stabilization of weight gain (Klein *et al.* 2006). Homeostatic Model Assessment for Insulin Resistance scores were significantly decreased and the number of subjects requiring referral for a glucose tolerance test was reduced among patients who received metformin. A subsequent meta-analysis has shown that weight benefits in adolescents come after 4 weeks of treatment, but due to concerns with the quality of the component clinical trials, more work is needed to definitively conclude a benefit from metformin (Ellul *et al.* 2018).

Weight gain is an even greater concern in the treatment of children and adolescents, who are more likely to be experiencing an initial exposure to antipsychotics and thus are more prone to rapid metabolic changes (Ballon *et al.* 2014). In a network meta-analysis of 28 RCTs, olanzapine showed significantly more weight gain compared with other antipsychotics in children and adolescents (Krause *et al.* 2018). These findings replicated the patterns seen in adults with regard to side effects.

Changes in weight, lipids, and insulin metabolism raise serious concerns for diabetes and related complications. Olanzapine is linked to both weight gain and insulin resistance and may cause both independently (Ballon *et al.* 2014). Just as in weight gain, olanzapine and clozapine have been consistently shown to pose the greatest risk for insulin resistance and diabetes (Zhang *et al.* 2017).

The accumulation of metabolic risk factors presents a great clinical conundrum in regard to olanzapine and clozapine. Although these drugs have been shown in the CATIE and other studies to have clinical superiority for antipsychotic effect, the metabolic side effects are so limiting as to make olanzapine a second-line agent in many cases. With FDA approval of the olanzapine/samidorphan combination in 2021 (Alkermes 2021), this may change, because the risk of weight gain is lower after 6 weeks of treatment (Correll *et al.* 2020). Results in early psychosis are still pending, however, and the overall metabolic impact other than weight gain has thus far not shown a significant difference. As this medication becomes available for wide-scale clinical use, further research will be warranted to determine whether use of this combination will make olanzapine a more attractive agent for use in the treatment algorithm.

In addition to the opioid antagonist approach to managing antipsychotic-induced weight gain, there is another mechanism under investigation utilizing glucocorticoid receptor antagonism. It has been shown that dysregulation of the hypothalamic-pituitary-adrenal axis has been implicated with the use of atypical antipsychotics (Baptista *et al.* 2004). A proof-of-concept study enrolled 66 healthy men in a 2-week double-blind RCT of miricorilant, an investigational mixed agonist/antagonist of the glucocorticoid receptor and a mineralocorticoid receptor antagonist with no progesterone activity that has shown efficacy in a rat model of olanzapine-induced weight gain (Hunt *et al.* 2021). Subjects who received olanzapine + miricorilant gained less weight than those given olanzapine + placebo (mean weight gain on day 15, 3.91 kg vs. 4.98 kg; difference between groups, [?] 1.07 kg; 95% CI, [?] 1.94 to [?] 0.19; P = 0.017). Compared with placebo, coadministration of miricorilant with olanzapine was associated with smaller increases in insulin, triglycerides, aspartate aminotransferase, and alanine aminotransferase. Two Phase II studies of miricorilant in patients with recent and long-standing antipsychotic-induced weight gain are currently in progress (NCT03818256 and NCT04524403).

There have been additional studies using mifepristone, a glucocorticoid receptor and progesterone receptor antagonist, showing similar results in rats and healthy adults (Beebe *et al.* 2006; Gross *et al.* 2009). The selective glucocorticoid receptor antagonism mechanism of CORT125281 has been studied in comparison with nonselective mifepristone in a mouse model for diet-induced obesity in which rhythmicity of circulating corticosterone levels was disturbed. The study showed that both compounds reduced body weight gain and fat mass; however, only CORT125281 restored the disturbed rhythmicity; lowered plasma levels of triglycerides, cholesterol, and free fatty acids; and strongly stimulated triglyceride-derived fatty acid uptake by brown adipose tissue depots (Kroon *et al.* 2018).

Other Side Effects

Among other side effects reported with olanzapine, sedation is frequent at the start of therapy but diminishes as patients develop tolerance for this side effect. In long-term treatment, the incidence of sedation is about 15%, similar to that of haloperidol. Prolactin elevations observed during olanzapine treatment occur early in treatment, and levels are much lower than those seen with risperidone or typical antipsychotics. Leukopenia is rare and occurs at a rate similar to that seen with other first-and second-generation antipsychotics, but olanzapine does not cause agranulocytosis, even in patients who developed this effect while taking clozapine. In animal toxicology studies and in clinical trials of olanzapine, no QTc prolongation was observed, and other cardiovascular effects were rarely of clinical importance (Cadario 2000).

Safety in Overdose

Reviews of case series and reports of olanzapine toxicity in adults describe predominantly circulatory and CNS effects, including coma, psychomotor agitation, hypertension and hypotension, tachycardia and bradycardia, hyperthermia and hypothermia, miosis and mydriasis, and QTc prolongation (QTc prolongation only with > 1,040 mg ingestion and in mixed overdoses) (Ciszowski *et al.* 2011; H. H. Tan *et al.* 2009). Olanzapine overdose was rarely fatal in the aforementioned case reports, and a systematic study of SGA overdose found that of 422 olanzapine overdoses, there were no fatalities, and 14% of patients required ventilation (Berling *et al.* 2016). Supportive care and careful cardiac, respiratory, and neurological monitoring for anticholinergic toxicity is generally the extent of treatment of olanzapine overdose, but a recent case report suggested using physostigmine to help diagnose and treat the toxidrome of olanzapine overdose (Serrano and Maldonado 2021). Very few data describe olanzapine overdose in children; available case report data are consistent with adult presentations of EPS and elevated prolactin levels (Tanoshima *et al.* 2013) and circulatory and neurological symptoms (McAllister *et al.* 2012).

Use in Pregnancy

The decision whether to continue use of olanzapine during pregnancy is important and complex for each individual. Potential risks of exposure must be balanced against the risks of relapse during and immediately after pregnancy. Exposure to olanzapine

was associated with a modest increase in risk of gestational diabetes in an analysis of Medicaid records (RR, 1.61), with 12% of women who stayed on olanzapine developing gestational diabetes compared with 4.7% of women who stopped olanzapine. This was a higher risk than with other antipsychotic drugs (Park *et al.* 2018). Overall, there is not an increased rate of birth defects for olanzapine (Betcher and Wisner 2020).

Drug-Drug Interactions

Olanzapine is metabolized primarily via glucuronidation and via oxidation by CYP1A2 (see "Pharmacokinetics and Disposition" earlier in this chapter). Other drugs that affect the activity of these metabolic pathways would therefore be expected to affect olanzapine pharmacokinetics. Indeed, drugs that inhibit CYP1A2 activity have been shown to decrease olanzapine clearance, thereby increasing olanzapine plasma concentrations.

Fluvoxamine, a known inhibitor of CYP1A2, has been shown to inhibit olanzapine metabolism in several studies. In an 11-day study of 10 healthy male smokers, coadministration of fluvoxamine (50-100 mg/day) with olanzapine (2.5-7.5 mg/day for 8 days [beginning on day 4]) resulted in an 84% increase in olanzapine peak serum concentrations (C_{max}) and a 119% increase in area under the plasma concentration-time curve over the last 24-hour dosing interval (AUC_{0-24}) compared with placebo coadministered with olanzapine. No change in half-life was observed in either olanzapine or 4'-*N*-desmethylolanzapine, suggesting that fluvoxamine inhibited olanzapine's first-pass metabolism (Maenpaa *et al.* 1997).

Fluoxetine and imipramine, although not known to be significant inhibitors of CYP1A2, when coadministered with olanzapine have been associated with small but statistically significant changes in olanzapine pharmacokinetics. Coadministration of fluoxetine with olanzapine resulted in a 15% decrease in olanzapine clearance and an 18% increase in C_{max}, with no significant difference in olanzapine half-life (Callaghan *et al.* 1999). Coadministration of imipramine with olanzapine resulted in an approximately 14% increase in olanzapine C_{max} and a non-statistically significant increase in olanzapine AUC of 19% (Callaghan *et al.* 1997).

Inducers of the CYP1A2 enzyme increase olanzapine clearance, thereby decreasing olanzapine systemic exposure. Carbamazepine, an inducer of several CYP enzymes (including CYP1A2), affects olanzapine disposition. A study in healthy volunteers reported that a single 10-mg dose of olanzapine taken after 2 weeks of pretreatment with carbamazepine (200 mg twice daily) had significantly higher clearance and apparent volume of distribution--but significantly lower C_{max}, AUC, and half-life--compared with a single 10-mg dose taken before carbamazepine treatment (Lucas *et al.* 1998).

Smoking, either tobacco or cannabis, is also known to induce CYP1A2 and can affect olanzapine disposition. The polycyclic aromatic hydrocarbons in smoke are responsible for inducing hepatic enzymatic metabolism (Desai *et al.* 2001). For this reason, dosage adjustments may be needed when a patient who smokes is placed in a smoke-free inpatient unit, even if adequate nicotine replacement is provided. Patients who decide to convert to noncombustible methods (e-cigarettes, vapes, edibles) will have a similar change in their olanzapine metabolism. Conversely, when there is a sudden increase in cigarette consumption (often associated with stress or impending relapse), a dosage increase may be needed to prevent an abrupt worsening of symptoms. A study comparing 19 male smokers with 30 male nonsmokers found that olanzapine clearance in smokers was 23% higher than that in nonsmokers (Callaghan *et al.* 1999). A population pharmacokinetic analysis of 910 patients receiving olanzapine found that drug clearance among nonsmokers was 37% lower in men and 48% lower in women than it was in the corresponding group of smokers (Patel *et al.* 1996). In vitro studies suggest that olanzapine does not significantly inhibit the activity of CYP1A2, CYP3A, CYP2D6, CYP2C9, or CYP2C19 (Ring *et al.* 1996a). In vivo studies suggest that olanzapine does not affect the disposition of aminophylline (Macias *et al.* 1998), diazepam, alcohol, imipramine (Callaghan *et al.* 1997), warfarin, biperiden, or lithium (Callaghan *et al.* 1999).

Conclusion

From review of the research focused on olanzapine, this compound, which has been approved for use in the United States since 1997, clearly has wide utility and some distinct advantages compared with traditional antipsychotics. In addition to its positive effects on a broad group of symptoms in schizophrenia, olanzapine is approved for the treatment of mania, both acute and long term, in bipolar disorder. Recent research has shown that olanzapine may be beneficial for disorders beyond psychosis (e.g., BPD, AN, PTSD, OCD). Olanzapine's high clinical efficacy and low risk of dystonia, parkinsonism, and tardive dyskinesia initially led to its greater acceptability in chronic schizophrenia and has encouraged clinicians to prescribe it for other conditions. The extension of olanzapine's uses is, in many ways, made possible by its low rate of movement disorders but is limited by significant metabolic concerns.

Olanzapine is not free from adverse effects; in addition to metabolic toxicity, there is also sedation, hypotension, and the black box warning regarding use in elderly patients limiting its use in some individuals. For this reason, olanzapine is not generally recommended as a first-line agent beyond the acute setting. However, its clinical utility toward the resolution of psychotic symptoms has prompted a significant effort to understand how to mitigate the metabolic side effects. Accordingly, the recently approved olanzapine/samidorphan combination, as well as new adjunctive weight-loss agents such as GLP-1 agonists, may allow olanzapine to be used more safely, thus affording more patients the opportunity to benefit from its clinical efficacy.

CHAPTER 28

Quetiapine

Peter F. Buckley, M.D.
Adriana E. Foster, M.D.

History and Discovery

Quetiapine is a second-generation antipsychotic (SGA) developed and subsequently marketed by AstraZeneca. In preclinical trials, quetiapine showed the features associated with antipsychotic efficacy and a low rate of motor effects (Goldstein 1999; Nemeroff *et al.* 2002). Quetiapine was approved in 1997 by the FDA for the treatment of schizophrenia; it was subsequently approved in Europe and in other countries worldwide. Additional approvals and indications for quetiapine's use in bipolar disorder, as well as approval of an extended-release (XR) formulation of quetiapine, have followed (Moller *et al.* 2007; Peuskens *et al.* 2007). The XR formulation has an additional indication as adjunctive treatment for major depressive disorder (MDD) for patients who show inadequate response to antidepressants alone.

Structure-Activity Relations

Quetiapine is an SGA of the dibenzothiazepine class (Figure 28-1). Its complex neuropharmacology includes a low binding profile for dopamine type 2 (D_2) receptors (Kapur *et al.* 2000). Indeed, given that an antipsychotic must occupy 60% or more of D_2 receptors to be clinically efficacious (Kapur *et al.* 2000), quetiapine's low D_2 binding--typically, approximately 30%--is noteworthy.

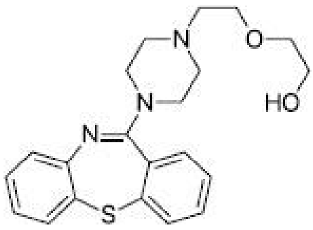

FIGURE 28-1. Chemical structure of quetiapine.

Source. PubChem Compound Database, National Center for Biotechnology Information. Available at: https://pubchem.ncbi.nlm.nih.gov/compound/5002#section=2D-Structure.

In attempting to reconcile this apparently subtherapeutic D_2 receptor antagonism with the well-recorded efficacy of quetiapine as an antipsychotic, Kapur *et al.* (2000) proposed an elegant *kiss and run hypothesis* to explain quetiapine's mechanisms of action. In a series of studies, they found that when D_2 receptor occupancy with quetiapine was measured with PET at shorter intervals (4 hours and 6 hours) than the conventional 12 hours after the last dose was taken, quetiapine did indeed show high D_2 occupancy. In contrast to other antipsychotics, quetiapine demonstrated a more rapid "run-off" from D_2 receptors; that is, there was rapid dissociation of the D_2 receptors (Kapur *et al.* 2000).

Like clozapine, quetiapine has strong binding at the 5-hydroxytryptamine (serotonin) type 2 (5-HT_2) receptors. This profile contrasts with its weak affinity for other subclasses of the serotonin receptor family (Nemeroff *et al.* 2002). Quetiapine also has strong affinity for a_1-noradrenergic receptors. This antagonism may relate to its propensity to induce postural hypotension, especially during rapid dosage titration. Additionally, quetiapine has strong antagonism at histamine type 1 (H_1) receptors. This probably relates to its sedative effect. H_1 receptor antagonism also appears to be a key contributor to weight gain during quetiapine therapy (Kim *et al.* 2007).

Pharmacokinetics and Disposition

Quetiapine is available in oral tablet formulations only (i.e., an immediate-release [IR] tablet and an extended-release [XR] tablet); there are no liquid or intramuscular preparations. Patients receiving IR tablets may be switched to the XR tablet at the equivalent total daily dosage, taken once daily. Individual dosage adjustments may be necessary (AstraZeneca 2020).

Quetiapine IR tablets may be taken with or without food (AstraZeneca 2020). The XR tablets should be taken either without food or with a light meal (500 calories). For the IR tablet formulation, peak blood levels are achieved in about 2 hours, with effective plasma levels sustained for approximately 6 hours (DeVane and Nemeroff 2001). The XR tablet reaches peak concentrations in about 6 hours. Although these pharmacokinetics provide the basis for the usual clinical regimen of twice-daily dosing, a short-term pilot study comparing once-daily dosing versus twice-daily dosing of the IR tablets demonstrated that the two regimens were equivalent in terms of efficacy and tolerability (Chengappa *et al.* 2003b). A PET study (Mamo *et al.* 2008) found comparable plasma levels and D_2 receptor occupancy between the IR and the XR formulation.

Quetiapine is metabolized by cytochrome P450 (CYP) 3A4 to inactive metabolites. The elimination half-life is about 7 hours, and steady state is reached within 2 days. Elderly patients may require a dosage reduction because oral clearance of quetiapine is reduced by about 40% in this population. Quetiapine dosages may need adjustment in the presence of liver disease (AstraZeneca 2013). Quetiapine has a major active metabolite, norquetiapine, with a half-life of approximately 12 hours at clinical dosages.

Coadministration of quetiapine with drugs that alter CYP3A4 activity is likely to result in clinically significant interactions. For example, the anticonvulsants carbamazepine and phenytoin are CYP3A4 inducers, and in their presence quetiapine dosages may need to be increased because of accelerated drug clearance (Potkin *et al.* 2002a, 2002b; Strakowski *et al.* 2002). Ritonavir, erythromycin, ketoconazole, and nefazodone are potent inhibitors of CYP3A4, and their concomitant use with quetiapine requires caution.

Clinical trials (Kahn *et al.* 2007; Lindenmayer *et al.* 2008) comparing the efficacy and tolerability of the XR formulation with the IR formulation indicated that quetiapine XR given once daily (at dosages of 400-800 mg/day) was effective for the treatment of schizophrenia and, on average, was similar in efficacy and tolerability to treatment with quetiapine IR. Similarly, it has been reported that XR and IR formulations achieve comparable efficacy for patients with bipolar disorder (Kishi *et al.* 2019). Regarding dosing of quetiapine, dosages for schizophrenia and mood disorder are similar, and lower dosages of quetiapine are typically reported in off-label use conditions such as anxiety disorders. A dose-response review of antipsychotics for schizophrenia suggested that 482 mg/day was the 95% effective dosage for quetiapine (Leucht *et al.* 2020). The quetiapine dosage equivalent to risperidone 1 mg/day was estimated at 77 mg/day. Quetiapine is excreted in the kidneys and is not affected by the individual's sex or smoking status. The metabolism of quetiapine is reduced by approximately 30% with advancing age (Goldstein 1999).

Indications and Efficacy

Quetiapine in the XR and IR formulations is FDA approved for the following indications in adults: treatment of schizophrenia; acute treatment of manic or mixed episodes associated with bipolar I disorder, both as monotherapy and as an adjunct to lithium or divalproex; acute treatment of depressive episodes associated with bipolar I or II disorder; and maintenance treatment of bipolar I disorder as an adjunct to lithium or divalproex. The XR formulation is also approved for use as an adjunct to antidepressant therapy in the treatment of MDD in adults.

In addition, quetiapine is efficacious in the treatment of schizophrenia and bipolar disorder in pediatric populations (Barzman *et al.* 2006; DelBello *et al.* 2007; McConville *et al.* 2000). The IR formulation is FDA approved for the treatment of schizophrenia in adolescents (ages 13-17 years) and the acute treatment of manic or mixed episodes associated with bipolar I disorder in children and adolescents (ages 10-17 years).

There are also reports of quetiapine's efficacy in treating anxiety disorders, OCD, borderline personality disorder, and Parkinson's disease. These uses have not been approved by the FDA. The use of any medication (in this case quetiapine) outside FDA-approved indications is not recommended in clinical practice.

Schizophrenia

Registration and early trials of quetiapine (Arvanitis and Miller 1997; Borison *et al.* 1996; Copolov *et al.* 2000; King *et al.* 1998; Peuskens and Link 1997; Small *et al.* 1997) demonstrated that quetiapine is an efficacious antipsychotic for the treatment of schizophrenia. Short-term (6-week) trials compared quetiapine, haloperidol, and placebo by using quetiapine at flexible daily dosages of [?] 250 mg or [?] 750 mg (Small *et al.* 1997) or fixed daily dosages of 75 mg, 150 mg, 300 mg, 600 mg, or 750 mg (Arvanitis and Miller 1997); the latter trial found that 300 mg/day was superior (but not statistically significantly so) to the lower and higher dosages and was the only dosage demonstrating efficacy for negative symptoms (Arvanitis and Miller 1997). These studies established a range of effective dosages for quetiapine and also suggested that dosages of [?] 250 mg/day were superior to lower dosages.

Subsequent studies helped refine quetiapine dosing strategies. An 8-week fixed-dosage comparison trial of quetiapine at 600 mg/day versus haloperidol at 20 mg/day showed similar efficacy for the two drugs for patients who were partial responders to first-generation antipsychotics (Emsley *et al.* 2000). A study comparing a rapid titration strategy (beginning at 200 mg/day, increasing to 800 mg/day by day 4) with a more conventional dosing strategy (50 mg/day on day 1, increasing up to 400 mg/day by day 5) showed similar efficacy and tolerability for the two strategies (Pae *et al.* 2007). Growing evidence from more recent studies (Honer *et al.* 2012; Lindenmayer *et al.* 2011) discourages the use of very-high-dosage quetiapine, and data are still lacking to indicate that dosages above 300 mg/day are more efficacious.

Most studies comparing quetiapine with either a first-generation antipsychotic or another SGA have reported similar efficacy for the agents in treating schizophrenia (Emsley *et al.* 2000; Peuskens and Link 1997; Small *et al.* 1997). A 4-month open-label trial of quetiapine and risperidone showed overall comparability between the two agents (Mullen *et al.* 2001). An 8-week comparative trial of quetiapine (with an average dosage of 525 mg/day) and risperidone (with an average dosage of 5.2 mg/day) also found the drugs similar in efficacy (Zhong *et al.* 2006). Quetiapine-treated patients had fewer extrapyramidal side effects (EPS), lower prolactin levels, and fewer sexual side effects. Whereas weight gain was similar in both treatment groups, quetiapine was more sedating and was more frequently associated with dry mouth than was risperidone. A 6-month study comparing quetiapine and risperidone reported better efficacy for risperidone (Potkin *et al.* 2006), with quetiapine associated with more polypharmacy. A 6-month double-blind comparative trial of quetiapine and olanzapine (Kinon *et al.* 2006) reported that quetiapine-treated patients were less likely to complete the study, although relapse rates were comparable overall in the two treatment groups. More weight gain occurred in olanzapine recipients. As yet, no studies have directly compared quetiapine with aripiprazole, iloperidone, asenapine, or lurasidone in the treatment of schizophrenia.

The most extensive comparative evaluation of quetiapine and other SGAs comes from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE). In the Phase I study, more quetiapine-treated patients than olanzapine-treated patients had discontinued treatment by 18 months (78% vs. 64%), and a similar (not statistically significant) trend was seen in comparisons of quetiapine versus risperidone, ziprasidone, or perphenazine (Lieberman *et al.* 2005). In the Phase II study, discontinuation rates favored clozapine and olanzapine over risperidone and quetiapine (McEvoy *et al.* 2006). The results from the tolerability pathways were mixed and showed similar efficacy for quetiapine versus other agents (Stroup *et al.* 2007). The findings relating to quetiapine's relative adverse-effect profile in this formative study are presented in the section "Side Effects and Toxicology." Another interesting analysis from the CATIE schizophrenia studies (Stroup *et al.* 2007) examined how the patients originally assigned to the perphenazine arm of the Phase I study fared. In this analysis, switching to quetiapine was more efficacious than switching to any of the other agents. Many of the efficacy and tolerability differences between agents observed in the CATIE schizophrenia studies have been attributed to differential dosing profiles.

An analogous comparative trial of quetiapine, risperidone, and olanzapine was conducted with patients experiencing a first episode of psychosis: the Comparison of Atypicals in First Episode of Psychosis (CAFE) study. Here, discontinuation rates were similar across drugs over the 1-year trial (McEvoy *et al.* 2007). Another pragmatic trial in first-episode psychosis (Gomez-Revuelta *et al.* 2020) found a higher rate of all-cause drug discontinuation at 3-year follow-up with quetiapine (95%) in comparison with haloperidol (89%), ziprasidone (79%), aripiprazole (73%), risperidone (71%), and olanzapine (69%). Two studies inform the comparative efficacy and tolerability of quetiapine in adolescents with psychosis (and related conditions) (Arango *et al.* 2014; Perez-Iglesias *et al.* 2014). Perez-Iglesias *et al.* (2014) found that quetiapine increased weight and cholesterol levels over 3 months. Similarly, Arango *et al.* (2014) found that quetiapine increased weight (less so than olanzapine, more so than risperidone) over 6 months in children and adolescents, although in this study there was no rise in cholesterol in quetiapine-treated patients. A 12-week comparative trial of quetiapine XR versus aripiprazole in youths ages 12-17 years with first episode psychosis also found similar increases in weight and metabolic parameters that were more pronounced in the quetiapine-treated group (Jensen *et al.* 2019).

The use of quetiapine for patients with prodromal features of schizophrenia has not yet been studied. A small study of quetiapine for patients with schizophrenia and comorbid substance abuse was inconclusive (Brunette *et al.* 2009).

Mood Disorders

There is evidence that quetiapine is an effective and well-tolerated antipsychotic for treating patients with bipolar mania and bipolar depression (Keramatian *et al.* 2021). Bowden *et al.* (2005) demonstrated that quetiapine was superior to placebo in the treatment of mania. In this multicenter study, significantly more patients treated with quetiapine than with placebo met criteria for response (> 50% decrease from baseline score on the Young Mania Rating Scale) at 7, 21, and 84 days. Building on initial evidence for mood effects that was derived from observations on mood assessment items in the pivotal schizophrenia trials, the Quetiapine Experience with Safety and Tolerability (QUEST) study compared quetiapine with risperidone in a 4-month open-label, flexible-dose trial (Mullen *et al.* 2001). This study included patients with schizophrenia, schizoaffective disorder, bipolar disorder, and depression. At week 16, the mean dosage of quetiapine was 317 mg/day, and the mean dosage of risperidone was 4.5 mg/day. Mean improvement on the Hamilton Rating Scale for Depression was significantly greater in quetiapine recipients than in risperidone recipients.

Calabrese *et al.* (2005) and Thase *et al.* (2006) have studied quetiapine use for patients with bipolar depression. In an 8-week trial, Calabrese *et al.* (2005) compared two dosages of quetiapine (300 mg/day and 600 mg/day) with placebo. Both dosages were efficacious, with improvements observed across the full range of depressive and anxiety symptoms. Fifty-eight percent of patients met a priori criteria for treatment response. Additionally, this antidepressant effect was observed with a once-daily dosage regimen. In a subsequent similar study (Thase *et al.* 2006) of the same two dosages

(300 mg/day and 600 mg/day), quetiapine was again compared with placebo in an 8-week trial of patients with bipolar depression. Again, both dosages of quetiapine showed efficacy across a broad range of depressive symptoms. These two studies led to FDA approval of quetiapine for treating bipolar depression.

Two large 8-week international multicenter studies--Efficacy of Monotherapy Seroquel in BipOLar DEpressioN (EMBOLDEN) I (Young *et al.* 2010) and II (McElroy *et al.* 2010)--compared quetiapine 300 mg/day and 600 mg/day with lithium 600-1,800 mg/day and placebo (EMBOLDEN I) and with paroxetine 20 mg/day and placebo (EMBOLDEN II) for patients with bipolar disorder with a major depressive episode. In the first study (Young *et al.* 2010), quetiapine at both dosages, but not lithium, led to significant improvement in symptoms of depression and anxiety. Compared with patients receiving placebo, patients treated with quetiapine 300 mg/day and 600 mg/day showed significant improvement on the Sheehan Disability Scale. In the second study (McElroy *et al.* 2010), quetiapine 300 mg/day and 600 mg/day, but not paroxetine 20 mg/day, led to significant improvement in depressive and anxiety symptoms. Neither lithium nor paroxetine led to significant functional improvement over placebo in these studies. In both studies, a small subgroup of patients with rapid-cycling bipolar disorder did not improve significantly from baseline with any of the drugs administered (quetiapine, lithium, or paroxetine).

In a long-term naturalistic study (Ketter *et al.* 2010) of quetiapine administered to 96 patients with bipolar disorder in a clinical setting, 38.5% of patients continued taking quetiapine for 328 days without the addition of other psychotropics, whereas 22.9% continued taking quetiapine for 613 days with the addition of another psychotropic, most often for depression. In a small double-blind, placebo-controlled pilot study (DelBello *et al.* 2009) of quetiapine 300-600 mg/day for depressed adolescents with bipolar disorder, quetiapine neither differentiated from placebo nor induced a significant change in symptoms from baseline to endpoint on measures of depressive, anxiety, or manic symptoms or clinical global impressions of bipolar disorder severity. Bourin *et al.* (2014) reported superior efficacy when lithium was added to quetiapine XR, and this combination was well tolerated.

Doree *et al.* (2007) reported that in a pilot study (*n* = 20), quetiapine was an efficacious augmenting agent for antidepressant treatment in MDD. Anderson *et al.* (2009) also reported on quetiapine's efficacy as an adjunctive treatment for patients with refractory depression. Quetiapine XR monotherapy at a mean daily dosage of 162.2 mg was shown to decrease symptoms of MDD at 8 weeks when compared with placebo (Bortnick *et al.* 2011). Cutler *et al.* (2009) reported that quetiapine XR 300 mg/day led to significantly higher rates of response and remission when compared with placebo in MDD, whereas quetiapine XR 150 mg/day had a significant effect only on response when compared with placebo. Quetiapine at dosages of 150-300 mg/day is now approved by the FDA as an adjunct to antidepressant treatment for a major depressive episode. In one of the studies leading to FDA approval of quetiapine XR for this indication, El-Khalili *et al.* (2010) demonstrated that quetiapine XR at 300 mg/day led to significant improvement in symptoms of depression from the first week of treatment when compared with placebo. In a review of registration studies for the MDD indication, McIntyre *et al.* (2009) concluded that quetiapine XR provides rapid and sustained relief of MDD symptoms. Weisler *et al.* (2012) also reported substantial improvement in depressive symptoms in two 6-week clinical trials of quetiapine XR. Remission at 6 weeks was achieved by 23.5% of patients

taking 150 mg/day and by 28.8% of patients taking 300 mg/day of quetiapine. A review of extant published studies of quetiapine--and other SGAs--in treatment-resistant depression suggests that augmentation of antidepressants with quetiapine can be an effective therapy for such hard-to-treat patients (Cantu *et al.* 2021). The review also suggested that quetiapine might have particular benefit for patients with treatment-resistant depression that includes features of marked anxiety or marked insomnia. A retrospective analysis of controlled trials also suggested that quetiapine might be helpful in so-called melancholic depression (Peters *et al.* 2020). Lin *et al.* (2014) used a national insurance database from Taiwan to compare in a mirror image design the effect of augmentation of antidepressant therapy over 1 year for patients with MDD. Quetiapine, olanzapine, and aripiprazole augmentations were each effective in reducing health care utilization. Masi *et al.* (2015) reported improvement from and tolerability of quetiapine in a small open-label study comparing quetiapine and risperidone for adolescents with bipolar disorder and comorbid conduct disorder.

Anxiety Disorders

The sedative or calming effect of quetiapine was well described in a variety of product registration trials (Chengappa *et al.* 2003a; Weiden *et al.* 2006), and studies in bipolar I disorder and bipolar depression (Calabrese *et al.* 2005; Hirschfeld *et al.* 2006; Thase *et al.* 2006) demonstrated improvements in anxiety symptoms with quetiapine. A systematic review of quetiapine for comorbid anxiety symptoms in patients with mood disorders affirmed that quetiapine can be beneficial for these symptoms (Crapanzano *et al.* 2021).

In a small 8-week study (Vaishnavi *et al.* 2007) of social anxiety disorder treatment, there was no significant difference in Brief Social Phobia Scale scores between the quetiapine and placebo groups, although people who took quetiapine did show a robust response as measured by Clinical Global Impression-Improvement scale scores.

Two small studies of quetiapine augmentation for patients with generalized anxiety disorder (GAD) who had not responded to antidepressant therapy (Katzman *et al.* 2008; Simon *et al.* 2008) yielded contradictory results. A large double-blind, randomized, placebo-controlled study of monotherapy for GAD (Bandelow *et al.* 2010) compared quetiapine XR 50 mg/day or 150 mg/day, paroxetine 20 mg/day, and placebo. Significant separation from placebo on the primary outcome variable (mean reduction in Hamilton Anxiety Scale total score) was seen for quetiapine XR 50 mg/day and 150 mg/day as early as 4 days into treatment, but not for paroxetine. After 8 weeks of treatment, both quetiapine 150 mg/day and paroxetine 20 mg/day had higher anxiety remission rates (Hamilton Anxiety Scale score [?] 7) compared with placebo. Weight gain [?] 7% of body weight was noted in a higher percentage of patients treated with quetiapine than of those taking placebo. In a parallel-group, double-blind, placebo-controlled study by Katzman *et al.* (2011), 432 patients with GAD were randomly assigned to continue long-term treatment with quetiapine XR (50 mg/day, 150 mg/day, or 300 mg/day) or to switch to placebo after an open-label run-in and stabilization period. During the randomized treatment period (from the point of random assignment to the end of the study), quetiapine XR significantly increased the time to occurrence of an anxiety event and decreased anxiety symptoms compared with placebo.

An analysis comparing the tolerability of quetiapine XR (dosages of [?] 300 mg/day) versus placebo in patients with different disorders found significantly higher rates of discontinuation due to adverse effects (DAEs) among patients with GAD, bipolar depression, or refractory MDD than among patients with schizophrenia or mania (Wang *et al.* 2011). In a systematic review and meta-analysis of all available trials of SGA medications, quetiapine was observed to have the most robust effect on anxiety symptoms (LaLonde and Van Lieshout 2011). The antianxiety effects of quetiapine were observed at lower dosages (typically 150 mg/day) than those used in schizophrenia studies, and the effects included overall improvement as well as remission. However, quetiapine was also associated with weight gain and high rates of medication DAEs in these studies of anxiety disorder (LaLonde and Van Lieshout 2011). In three 8-week studies of quetiapine XR, Stein *et al.* (2011) reported DAE rates of 13%, 16%, and 24% for quetiapine dosages of 50 mg/day, 150 mg/day, and 300 mg/day, respectively. In an 8-week placebo-controlled comparative trial of quetiapine XR and escitalopram, comparable improvements in anxiety symptoms, occurring early in the study, were observed with quetiapine and escitalopram (Merideth *et al.* 2012). By contrast, in an 8-week trial in a more "real-world" population of patients with bipolar depression with substantial comorbidities (especially GAD), quetiapine XR showed no advantages over placebo (Gao *et al.* 2014).

At present, the FDA has not approved quetiapine for use in any anxiety disorder.

Other Disorders

Several small studies of quetiapine augmentation (at dosages up to 400 mg/day) of selective serotonin reuptake inhibitor pharmacotherapy in refractory OCD yielded contradictory results (Atmaca *et al.* 2002; Carey *et al.* 2005; Fineberg *et al.* 2005); although improvement in Yale-Brown Obsessive Compulsive Scale (Y-BOCS) scores was noted in patients treated with quetiapine, the response to quetiapine did not differentiate from placebo. Quetiapine's efficacy as an augmenting agent with antidepressants in treatment-resistant OCD was recently reviewed in a meta-analysis of five double-blind randomized controlled trials (RCTs) (Komossa *et al.* 2010). Adjunctive quetiapine was not superior to placebo in reducing Y-BOCS scores by 25% (the criterion for response in these studies), but it did reduce the Y-BOCS scores more significantly by the endpoint compared with placebo. A small case series also showed that adjunctive quetiapine response may be enduring (Dell'Osso *et al.* 2006). Veale *et al.* (2014) conducted a meta-analysis of SGAs in OCD. In contrast to benefits seen with risperidone or aripiprazole, no effect was seen with augmentation with either quetiapine or olanzapine. A study of quetiapine augmentation for patients with refractory OCD showed comparable efficacy between quetiapine and aripiprazole over a 4-month treatment period (Talaei *et al.* 2020).

Quetiapine has been studied in the treatment of PTSD (Ahearn *et al.* 2006; Byers *et al.* 2010; Hamner *et al.* 2003; Kozaric-Kovacic and Pivac 2007; Sokolski *et al.* 2003; Stathis *et al.* 2005). All but one of the studies (Stathis *et al.* 2005) involved quetiapine being administered to veterans as an adjunctive agent added to selective serotonin reuptake inhibitors, other antidepressants, sedative-anxiolytics, or anticonvulsants. All were open-label studies, and with the exception of a retrospective chart review comparing quetiapine with the a_1 receptor antagonist prazosin (Byers *et al.* 2010), none had a comparison group. The average quetiapine dosage used in these studies was 100-335 mg/day administered for 6-8 weeks. Quetiapine decreased symptoms of avoidance, hyperarousal, and intrusive recollection in the populations studied.

Other Conditions and Patient Populations

Quetiapine has also been used for older adults. In a 1-year open-label trial of quetiapine treatment for 151 older adults (mean age 76.8 years) with psychotic disorders (McManus *et al.* 1999), 52% of patients showed symptom improvement (as measured by a 20% or greater decline in Brief Psychiatric Rating Scale total score). Seventy percent of patients had some organic condition, predominantly Alzheimer's disease, with the remaining patients having a diagnosis of schizophrenia, schizoaffective disorder, or delusional disorder. Quetiapine was well tolerated at a mean dosage of 100 mg/day. A 10-week study comparing two dosages of quetiapine (100 mg/day and 200 mg/day) with placebo for nursing home residents with dementia and agitation (Zhong *et al.* 2007) reported that only the 200 mg/day quetiapine dosage was efficacious in treating agitation. Quetiapine (100 mg/day) was also compared with risperidone (1.0 mg/day), olanzapine (5.5 mg/day), and placebo over 36 weeks in the CATIE Alzheimer's disease study (Schneider *et al.* 2006). Overall, no effect on the Alzheimer's Disease Cooperative Study-Clinical Global Impression of Change scale score was seen with any of the agents, and there were no differences between agents in time to discontinuation.

In contrast to the encouraging findings from open-label studies of quetiapine for Parkinson's-associated psychosis, four of five later double-blind RCTs

(Kurlan *et al.* 2007; Ondo *et al.* 2005; Rabey *et al.* 2007; Shotbolt *et al.* 2009) found no benefit for quetiapine in this population. The single positive RCT (Fernandez *et al.* 2009) was small ($N = 16$) and excluded patients with delusions, which appear to be more difficult to treat than hallucinations in Parkinson's disease (Shotbolt *et al.* 2010). Another recent review of available clinical trials between 1991 and 2017 came to a similar conclusion that quetiapine's efficacy for psychosis in Parkinson's disease is not as favorable as originally thought (Chen *et al.* 2019).

Agitation is a core aspect of several conditions. Currier *et al.* (2006) reported an interesting study of quetiapine in agitated patients in the emergency department. Here, Currier and colleagues reported that quetiapine could be used as an acute antiagitation agent if the dosage titration was judicious. Postural hypotension was observed in this study. A study of quetiapine used to manage delirium for critical care patients showed prospectively that quetiapine did not induce QTc prolongation in this potentially at-risk population (Lee *et al.* 2019). Other studies of quetiapine and agitation report benefits in treating hostility both for adults with schizophrenia (Chengappa *et al.* 2003a) or bipolar disorder (Buckley *et al.* 2007) and for children with hostile behaviors (Barzman *et al.* 2006; Findling *et al.* 2007).

Black *et al.* (2014) examined low-dosage quetiapine (150 mg/day) and moderate-dosage quetiapine (300 mg/day) versus placebo in an 8-week, double-blind trial of inpatients with borderline personality disorder. Both dosages of quetiapine were effective across a range of symptoms for these patients, although there were more side effects with moderate-dosage quetiapine.

Side Effects and Toxicology

To illustrate the profile of adverse effects typically seen with quetiapine, we have tabulated the results from an 8-week RCT (Zhong *et al.* 2006) (Table 28-1) in which quetiapine was compared with risperidone. Overall, quetiapine was well tolerated, with only 6% of patients discontinuing treatment because of adverse effects.

TABLE 28-1. Comparative side-effect profile of quetiapine versus risperidone: adverse effects present in [?] 5% of patients in an 8-week study

Adverse effect	Quetiapine (*n* = 338; median dosage 525 mg/day), *n* (%)	Risperidone (*n* = 334; median dosage 5.2 mg/day), *n* (%)	*P* value*
Somnolence	89 (26.3)	66 (19.7)	0.044
Headache	51 (15.1)	56 (16.7)	0.599
Weight gain	48 (14.2)	45 (13.4)	0.824
Dizziness	48 (14.2)	32 (9.6)	0.0737
Dry mouth	41 (12.1)	17 (5.1)	< 0.01
Dyspepsia	22 (6.5)	26 (7.8)	0.552
Nausea	21 (6.2)	22 (6.6)	0.876
Pain	21 (6.2)	24 (7.2)	0.536
Asthenia	17 (5.0)	14 (4.2)	0.714
Agitation	17 (5.0)	10 (3.0)	0.238
Pharyngitis	15 (4.4)	24 (7.2)	0.140
Akathisia	13 (3.8)	28 (8.4)	0.016
Vomiting	13 (3.8)	18 (5.4)	0.364
Dystonia	1 (0.3)	18 (5.4)	< 0.001

Source. Adapted from Zhong *et al.* 2006.

On average, the adverse-effect profile of the XR formulation of quetiapine is similar to that of the IR formulation.

Somnolence, Sedation, and Dizziness

Somnolence is a common side effect of quetiapine that probably relates to its antihistaminergic activity. Although somnolence occurs early in treatment and generally decreases over time, it may persist in some patients. It may also cause patients to stop taking their medication, because sedation is generally a poorly tolerated side effect. In the bipolar depression study by Calabrese *et al.* (2005), somnolence was observed in 24% of patients taking quetiapine at a dosage of 300 mg/day and in 27% of patients taking 600 mg/day. In the long-term study by Ketter *et al.* (2010), sedation was present in 19.8% of patients. Dizziness is another troublesome side effect, and it may be associated with postural hypotension, an effect that is of even greater concern. As with sedation, dizziness can sometimes cause discontinuation of quetiapine therapy. A thoughtful review (Modesto-Lowe *et al.* 2021) of quetiapine's sedative effect evaluated the data on off-label use of quetiapine for insomnia.

Metabolic Effects

There is major concern about antipsychotic-induced weight gain and metabolic disturbances (Allison *et al.* 1999; Newcomer 2005; Newcomer *et al.* 2002). Quetiapine is clearly associated with weight gain, although the weight gain effect is not as great as

that seen with clozapine or olanzapine. On the other hand, the weight gain effect of quetiapine is greater than that of ziprasidone or aripiprazole (Newcomer 2005) and that of the newer agents asenapine (Allergan 2021) and lurasidone (Sunovion 2022).

In an 8-week comparative study by Zhong *et al.* (2006), weight gain that was clinically significant (a 7% increase above baseline weight) was observed in 10.4% of patients taking quetiapine and in 10.5% of patients taking risperidone. In the Phase I CATIE study, quetiapine had a moderate effect on weight (and other aspects of the metabolic profile) compared with other agents (Lieberman *et al.* 2005). Those data are shown in Table 28-2. In the first-episode CAFE study, quetiapine had a less favorable weight-effects profile than olanzapine or risperidone. Eighty percent of patients taking quetiapine gained weight, compared with 50% of those taking olanzapine and 2% of those taking risperidone. Interestingly, female patients taking quetiapine were less likely than male patients to gain weight in this 1-year study of patients treated for their first episode of psychosis (Patel *et al.* 2009). It is also important to consider quetiapine's propensity to induce weight gain among patients with bipolar disorder (especially because these patients may also be taking lithium or valproic acid). In the 8-week EMBOLDEN I (Young *et al.* 2010) and

EMBOLDEN II (McElroy *et al.* 2010) studies, weight gain of more than 7% of baseline weight was present in 4.6% and 9%, respectively, of patients taking quetiapine 300 mg/day, compared with 8.3% and 11.3%, respectively, of those taking quetiapine 600 mg/day. In EMBOLDEN I and EMBOLDEN II, the average weight gains in quetiapine-treated patients were 0.6 kg and 1.1 kg, respectively, for the 300 mg/day groups and 0.8 kg and 1.7 kg, respectively, for the 600 mg/day groups. A recent review of adverse effects of several SGAs in more pragmatic trials suggested a more complex assessment of risk, with mixed results for quetiapine with respect to the development of diabetes and dyslipidemia (Bernardo *et al.* 2021), although the rigor of the studies included limits the generalizability of findings.

TABLE 28-2. Comparative metabolic profiles of antipsychotics in the Phase I CATIE schizophrenia trial: change from baseline

	Olanzapine	**Quetiapine**	**Perphenazine**	**Risperidone**	**Ziprasidone**	***P* value**
Weight gain > 7%, *n*/total *N* (%)	92/307 (30)	49/305 (16)	29/243 (12)	42/300 (14)	12/161 (7)	< 0.001
Weight change (lb), mean +- SE	9.4 +- 0.9	1.1 +- 0.9	2.0 +- 1.10	0.8 +- 0.9	[?] 1.6 +- 1.10	< 0.001
Blood glucose change (mg/dL), exposure-	13.7 +- 2.50	7.5 +- 2.5	5.4 +- 2.8	6.6 +- 2.5	2.9 +- 3.4	0.59

Note. *P* values for laboratory values and for the change in weight are based on ranked analysis of covariance with adjustment for whether patients had an exacerbation in the preceding 3 months and the duration of exposure to the study drug in Phase I. Mean values for metabolic factors (other than weight change) were also adjusted for duration of exposure to the study drug.

SE = standard error.

Source. Adapted from Table 3 (p. 1220) in Lieberman *et al.* 2005.

	Olanzapine	**Quetiapine**	**Perphenazine**	**Risperidone**	**Ziprasidone**	***P* value**
adjusted mean +- SE						
Glycosylated hemoglobin change (%), exposure-adjusted mean +- SE	0.40 +- 0.07	0.04 +- 0.08	0.09 +- 0.09	0.07 +- 0.08	0.11 +- 0.09	0.01
Cholesterol change (mg/dL), exposure-adjusted mean +- SE	9.4 +- 2.4	6.6 +- 2.4	1.5 +- 2.7	[?] 1.3 +- 2.40	[?] 8.2 +- 3.20	< 0.001
Triglycerides change (mg/dL), exposure-adjusted mean +- SE	40.5 +- 8.90	21.2 +- 9.20	9.2 +- 10.1	[?] 2.4 +- 9.10	[?] 16.5 +- 12.20	< 0.001

Note. P values for laboratory values and for the change in weight are based on ranked analysis of covariance with adjustment for whether patients had an exacerbation in the preceding 3 months and the duration of exposure to the study drug in Phase I. Mean values for metabolic factors (other than weight change) were also adjusted for duration of exposure to the study drug.

SE = standard error.

Source. Adapted from Table 3 (p. 1220) in Lieberman *et al.* 2005.

In the bipolar depression study by Calabrese *et al.* (2005), the mean increases in glucose levels were 6 mg/dL and 3 mg/dL with quetiapine dosages of 600 mg/day and 300 mg/day, respectively. In the comparative study of quetiapine and risperidone in the treatment of schizophrenia (Zhong *et al.* 2006), the mean increases from baseline in fasting glucose levels were 1.8 mg/dL with quetiapine and 5.6 mg/dL with risperidone. The metabolic profile of quetiapine appeared moderate in the Phase I CATIE schizophrenia study (see Table 28-2. Newcomer *et al.* (2009) conducted a euglycemic clamp study of quetiapine and found little evidence of insulin insensitivity. A recent meta-analysis by the Cochrane group involving head-to-head comparisons of SGAs (Komossa *et al.* 2010) found that quetiapine was associated with significantly greater cholesterol elevations than risperidone (mean difference 8.61 mg/dL) and ziprasidone (mean difference 16.01 mg/dL). In the CATIE Phase I trial (Lieberman *et al.* 2005), which included patients with chronic schizophrenia, quetiapine led to a mean change from baseline fasting triglyceride levels of + 19.2 mg/dL, whereas a mean change of + 42.9 mg/dL was observed for olanzapine, + 8.3 mg/dL for perphenazine, [?] 2.6 mg/dL for risperidone, and [?] 18.1 mg/dL for ziprasidone. In a population of young patients with early psychosis treated with quetiapine, olanzapine, or risperidone, the CAFE study (Patel *et al.* 2009) found that elevations in fasting triglyceride levels at 52 weeks were significantly greater in quetiapine-treated patients than in risperidone-treated patients (44.3 vs. 8.2 ng/mL, respectively). Correll *et al.* (2014) reported baseline results from the pragmatic study Recovery After an Initial Schizophrenia

Episode. All patients were in their first episode of psychosis, with less than 6 months of exposure to antipsychotics. Use of quetiapine was associated with a high ratio of triglycerides to high-density lipoprotein cholesterol. The extent to which patients transition during treatment from a normative metabolic state to dysregulation is also informative. In the first-episode CAFE study, treatment-emergent metabolic syndrome was observed among 51 patients (13.4% of the population in a study where 4.3% met metabolic syndrome criteria at study onset), with a distribution of 22 patients taking olanzapine, 18 taking quetiapine, and 11 taking risperidone (Patel *et al.* 2009). Another recent study of antipsychotic use by adolescents found an elevated risk of type 2 diabetes mellitus, with longer duration of antipsychotic exposure and olanzapine use each conferring greater risk (Correll *et al.* 2014). In another first-episode comparative study, Perez-Iglesias *et al.* (2014) found that patients with first-episode psychosis treated with quetiapine, aripiprazole, or ziprasidone gained weight over 12 weeks of treatment, with a greater than 7% weight increase noted for 32% of patients receiving quetiapine, 45% of those receiving aripiprazole, and 23% of those receiving ziprasidone. Quetiapine and aripiprazole were also associated with greater increases in total cholesterol and low-density lipoprotein cholesterol. Overall, quetiapine appears to carry a risk of causing weight gain and other metabolic disturbances. The potential that quetiapine may preferentially raise triglycerides is noteworthy, given that this effect could be a harbinger for later insulin resistance. This observation merits further consideration and vigilance over time.

Quetiapine is associated with a low risk of raising prolactin levels (Hamner *et al.* 1996; Lieberman *et al.* 2005; Small *et al.* 1997; Zhong *et al.* 2006).

Extrapyramidal Side Effects

The low-EPS advantage of quetiapine is compelling and consistent across studies. In the Seroquel Patient Evaluation on Changing Treatment Relative to Usual Medication switch study (Larmo *et al.* 2005), switching to quetiapine from haloperidol, olanzapine, or risperidone was associated with a robust reduction in EPS. This low propensity for EPS was also seen in the bipolar depression studies (Calabrese *et al.* 2005; Thase *et al.* 2006).

Cardiovascular Effects

Quetiapine's prescribing information (AstraZeneca 2013, 2020) carries a boxed warning similar to that required in the prescribing information of many other antipsychotics concerning cardiovascular risks. However, the CATIE trial found no evidence of a heightened QTc risk with quetiapine relative to other SGAs and perphenazine (Lieberman *et al.* 2005).

Other Effects

The potential of quetiapine to induce cataracts was studied in a pragmatic follow-up trial of patients (N = 37; mean age 23 years) with first-episode psychosis that included regular slit-lamp ophthalmological examinations (Whitehorn *et al.* 2004). After exposure to quetiapine 500-600 mg/day for a mean of 22.4 months, none of the patients developed any ocular changes. Most clinicians do not obtain specialist eye examinations when prescribing quetiapine.

Abnormalities in thyroid hormone levels were observed in the large premarketing trials of quetiapine (Arvanitis and Miller 1997). A small RCT did find lower total thyroid hormone levels with quetiapine use but no significant changes in free thyroxine or thyroid-stimulating hormone levels (Kelly and Conley 2005). Constipation, abdominal pain, and hypotension have also been associated with quetiapine use (AstraZeneca 2013).

A curious and unsubstantiated claim is that quetiapine might have abuse potential (Pierre *et al.* 2005; Pinta and Taylor 2007). This observation merits further consideration and vigilance.

Use During Pregnancy

As is the case with all SGAs, there is little information about the effects of quetiapine during pregnancy. A prospective study by McKenna *et al.* (2005) examined a sample of pregnant women in Canada, Israel, and England treated with SGAs, which was matched to a comparison group of pregnant women who were not exposed to these agents. Among them were 36 women treated with quetiapine. The pregnancy outcomes in the exposed and comparison groups were not significantly different, with the exceptions of the rate of low birth weight, which was 10% in exposed babies and 2% in the comparison group ($P = 0.05$), and the rate of therapeutic abortions, which was 9.9% in exposed women and 1.3% in the comparison group ($P = 0.003$). These findings suggest that atypical antipsychotics as a group are not associated with an increased risk for major malformations. Cohen *et al.* (2018) reported data from a national pregnancy registry for atypical antipsychotics and found no evidence for heightened risk of major malformations after first trimester exposure to quetiapine.

Conclusion

Quetiapine is now a well-established and widely prescribed antipsychotic. As detailed earlier, there is strong evidence for its efficacy in all of the current FDA-approved indications. Quetiapine is also used extensively under circumstances not approved by the FDA (i.e., off-label use), and evidence for its efficacy in some of these uses has been reviewed in this chapter. Additional clinical trials of quetiapine are ongoing (www.clinicaltrials.gov).

CHAPTER 29

Risperidone and Paliperidone

Leonardo V. Lopez, M.D.
Michele Hill, MRCPsych
Donald C. Goff, M.D.

Risperidone and paliperidone are atypical antipsychotics frequently used in the treatment of primary psychotic disorders, as well as in the treatment of a variety of other psychiatric conditions, including affective, compulsive, and neurodevelopmental disorders. In this chapter, we describe the molecular and pharmacological properties of these two related compounds and review the evidence supporting their use in the treatment of psychiatric disorders.

History and Discovery

A decade before clozapine was approved for marketing in the United States, Janssen Pharmaceuticals established a program to examine the potential role of serotonergic agents in schizophrenia. Early interest in serotonergic agents stemmed from preclinical literature demonstrating that both behavioral effects of dopamine receptor agonists and haloperidol-induced catalepsy could be modulated by serotonin$_2$ (5-HT$_2$) receptor antagonists; in addition, the early butyrophenone derivative pipamperone, which was observed to reduce agitation and improve social activity for patients with severe depression, was found to possess primarily 5-HT_2 receptor antagonist activity (Ansoms *et al.* 1977; Leysen *et al.* 1978).

In 1981, Janssen Pharmaceuticals developed setoperone, a 5-HT_2 receptor antagonist with weak $dopamine_2$ (D_2) receptor antagonism that displayed antipsychotic effects and efficacy for negative symptoms in a preliminary open trial (Ceulemans *et al.* 1985). Janssen Pharmaceuticals additionally synthesized a selective 5-HT_{2A} and 5-HT_{2C} receptor antagonist, ritanserin, which was shown to decrease extrapyramidal side effects

(EPS) when combined with haloperidol in at studies. Ritanserin also was active in animal models of anxiety (Colpaert *et al.* 1985; Meert and Colpaert 1986) and partially ameliorated the behavioral effects of lysergic acid diethylamide (LSD) (Colpaert *et al.* 1985). In placebo-controlled trials of patients with chronic schizophrenia, addition of ritanserin to first-generation antipsychotics (FGAs) reduced negative symptoms and EPS (Bersani *et al.* 1990; Duinkerke *et al.* 1993; Gelders 1989; Reyntjens *et al.* 1986). Concluding that 5-HT_2 receptor antagonism might increase the effectiveness of D_2 blockers, particularly for negative symptoms, and reduce EPS, but that it was not sufficiently effective as monotherapy, Paul Janssen and colleagues undertook development of risperidone, which combined potent 5-HT_{2A} and D_2 receptor blockade.

After extensive preclinical characterization (Janssen *et al.* 1988), risperidone was first studied in clinical trials in 1986 and received FDA approval for marketing in the United States in 1994. By the time risperidone became available to clinicians, the prominence of theories citing 5-HT_2 enhancement of D_2 receptor antagonism as a primary mechanism for clozapine's atypical properties (Meltzer *et al.* 1989), as well as the evidence from registration trials of reduced EPS and greater efficacy compared with high-dose haloperidol, resulted in enthusiasm for the first of the "serotonin dopamine antagonists." Risperidone was rapidly incorporated into clinical practice in the United States, where within 2 years it became the most frequently prescribed antipsychotic agent. In 2003, risperidone microspheres (Consta) received FDA approval as the first long-acting second-generation antipsychotic (SGA) designed for intramuscular injection. In December 2006, Janssen Pharmaceuticals introduced paliperidone (9-hydroxyrisperidone), the active metabolite of risperidone, formulated as an extended-release tablet marketed under the brand name Invega. Extended-release paliperidone is approved for the treatment of schizophrenia and schizoaffective disorder. A long-acting depot preparation, paliperidone palmitate (Sustenna), received FDA approval for schizophrenia in 2009 and for schizoaffective disorder in 2014; it was the first once-monthly depot formulation of an SGA to become available in the United States. In May 2015, a new formulation of paliperidone with a 3-month injection interval, paliperidone palmitate 3-month formulation (PP3M; Invega Trinza), was approved by the FDA for the treatment of schizophrenia under its priority review process. This formulation's 3-month schedule provides the longest dosing interval available for patients with schizophrenia.

Structure-Activity Relations and Pharmacological Profile

Risperidone, or 3-[2-(4-[6-fluoro-1,2-benzisoxazol-3-yl]-1-piperidinyl)ethyl]-6,7,8,9-tetrahydro-2-methyl-4H-pyrido[1,2-a]pyrimidin-4-one, is a benzisoxazole derivative characterized by very high affinity for 5-HT$_{2A}$ receptors and moderately high affinity for D$_2$, histamine 1 (H$_1$), and a$_1$- and a$_2$-adrenergic receptors (Figure 29-1). In vitro, the affinity of risperidone for 5-HT$_{2A}$ receptors is roughly 10 to 20 times greater than that for D$_2$ receptors (Leysen *et al.* 1994; Schotte *et al.* 1996); in vivo binding to rat striatal D$_2$ receptors occurs at a dosage 10 times higher than does binding to 5-HT$_{2A}$ receptors (Leysen *et al.* 1994). The affinity for 5-HT$_{2A}$ receptors is more than 100 times greater than for other serotonin receptor subtypes.

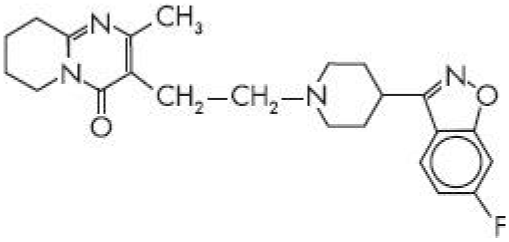

FIGURE 29-1. Chemical structure of risperidone.

Risperidone's active metabolite 9-hydroxyrisperidone (paliperidone) (Figure 29-2) has a similar receptor affinity profile, although paliperidone has lower affinity for a_1- and a_2-adrenergic receptors. Both risperidone and paliperidone display a high affinity for 5-HT_{2A} receptors in rat brain tissue and for cloned human receptors expressed in COS-7 cells (Leysen *et al.* 1994). Risperidone binds to 5-HT_{2A} receptors with approximately 20 times greater affinity compared with clozapine and 170 times greater affinity compared with haloperidol (Leysen *et al.* 1994).

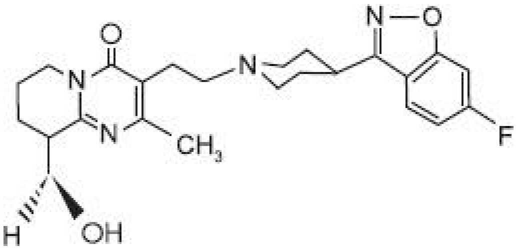

FIGURE 29-2. Chemical structure of paliperidone.

The affinity of risperidone for D_2 receptors is approximately 50 times greater than that of clozapine and approximately 20%-50% that of haloperidol (Leysen *et al.* 1994) (Table 29-1). Binding affinity for D_2 receptors was similar in rat mesolimbic and striatal tissue and in the long and short forms of cloned human D_2 receptors expressed in embryonic kidney cells (Leysen *et al.* 1993a). The affinities of risperidone and paliperidone for dopamine$_4$ (D_4) and dopamine$_1$ (D_1) receptors are similar to those of clozapine and haloperidol (Leysen *et al.* 1994). Risperidone and paliperidone have essentially no affinity for muscarinic acetylcholine receptors and modest H_1 receptor activity. Unlike haloperidol, risperidone does not bind to sigma sites (Leysen *et al.* 1994). However, compared with other agents, including paliperidone, risperidone has a high affinity for a_2-adrenergic receptors that is substantially greater than that of clozapine or any FGA and that approaches the affinity of phentolamine (Richelson 1996). The affinity of risperidone for a_1-adrenergic receptors is roughly comparable to that of chlorpromazine and approximately 5-10 times greater than that of clozapine (Leysen *et al.* 1993b; Richelson 1996). The median effective dose of risperidone needed to inhibit D_2-mediated apomorphine-induced stereotypies in rats is 0.5 mg/kg; at this dosage, approximately 40% of D_2 receptors are occupied, as are 80% of 5-HT_{2A} receptors, 50% of H_1 receptors, 38% of a_1-adrenergic receptors, and 10% of a_2-adrenergic receptors (Leysen *et al.* 1994).

Several groups have studied the occupancy of D_2 and 5-HT_2 receptors in patients with schizophrenia, using PET or SPECT ligand-binding techniques. Kapur *et al.* (1999) used PET to measure D_2 occupancy with ^{11}C-labeled raclopride and 5-HT_2 occupancy with ^{18}F-labeled setoperone in patients with chronic schizophrenia maintained on a stable clinician-determined dosage of risperidone. The PET was performed 12-14 hours after the last dose of risperidone. Occupancy of D_2 receptors ranged from 63% to 89%; 50% occupancy was calculated to occur with a daily risperidone dosage of 0.8 mg. Similar ranges have been found with paliperidone dosages between 3 and 15 mg/day, with 50% occupancy occurring at approximately 2.5 mg/day (Arakawa *et al.* 2008). Patients treated with risperidone (6 mg/day) exhibited a mean D_2 occupancy of 79%, which was consistent with the mean occupancy of 82% previously reported by Nyberg *et al.* (1999) and would be expected to exceed the putative threshold for EPS for some patients. A similar degree of D_2 occupancy was calculated to occur with olanzapine at approximately 30 mg/day (Kapur *et al.* 1999). A maximal 5-HT_2 occupancy of greater than 95% was achieved with risperidone at daily dosages as low as 2-4 mg. In a small sample of patients treated biweekly for at least 10 weeks with risperidone microspheres (Consta), Remington *et al.* (2006) found that the 25 mg dose produced a mean D_2 occupancy of 54% (preinjection) and 71% (postinjection), whereas the 50-mg dose produced occupancy levels of 65% (preinjection) and 74% (postinjection). Arakawa *et al.* (2008) found a D_2 occupancy of 58% with paliperidone at 3 mg/day and 77% with 9 mg/day, consistent with clinical estimates that paliperidone is roughly half as potent as risperidone, perhaps because of reduced bioavailability (de Leon *et al.* 2010).

Preclinical characterization of risperidone in rats revealed more potent antiserotonergic activity compared with ritanserin in all tests (Janssen *et al.* 1988). For example, in reversal of tryptophan-induced effects in rats, risperidone was 6.4 times more potent than ritanserin for reversal of peripheral 5-HT$_2$-mediated effects and 2.4 times more potent for reversal of centrally mediated 5-HT$_2$ effects (Janssen *et al.* 1988). Risperidone was also found to completely block discrimination of LSD, in contrast to the partial attenuation observed with ritanserin (Meert *et al.* 1989). Although risperidone demonstrated activity in all dopamine-mediated tests, the dose-response pattern differed from that of haloperidol (Janssen *et al.* 1988). The two drugs were roughly equipotent for inhibition of certain dopamine effects, such as amphetamine-induced oxygen hyperconsumption, whereas the dosage of risperidone necessary to cause pronounced catalepsy in rats was 18 times higher than that of haloperidol (Janssen *et al.* 1988). Risperidone depressed vertical and horizontal activity in rats at a dosage 2-3 times greater than that of haloperidol but required dosages more than 30 times greater than those of haloperidol to depress small motor movements (Megens *et al.* 1988).

Pharmacokinetics and Disposition

Risperidone is rapidly absorbed after oral administration, with peak plasma levels achieved within 1 hour (Heykants *et al.* 1994). In early Phase I studies, risperidone demonstrated linear pharmacokinetics at dosages between 0.5 and 25 mg/day (Mesotten *et al.* 1989; Roose *et al.* 1988).

After a single dose of the extended-release formulation of paliperidone (Invega), serum concentrations gradually increase until a maximum concentration is achieved approximately 24 hours after ingestion. Absorption of paliperidone is approximately 50% greater when taken with a meal compared with the fasting state. Extended-release paliperidone also demonstrates dose-proportional pharmacokinetics within the recommended dosing range (3-12 mg/day).

Because risperidone lacks a hydroxyl group to which an ester can be bound for a traditional oil-based depot preparation, polymer microsphere technology was used to produce a slow-release injectable formulation. Risperidone microspheres do not begin to release appreciable amounts of drug until 3 weeks after injection and continue to release drug for approximately 4 weeks, with maximal drug release occurring about 5 weeks after injection.

Paliperidone palmitate is an esterified form of paliperidone and is poorly soluble in water. It dissolves slowly after intramuscular injection, after which it is hydrolyzed to active paliperidone and absorbed into the systemic circulation. Systemic availability of paliperidone begins on day 1 and can last as long as 126 days after injection. Maximum blood levels are achieved a median of 13 days after injection. A dosage of 117 mg/month is recommended by the manufacturer; a study from the United Kingdom revealed a mean dosage in clinical practice of approximately 110 mg/month (Deslandes *et al.* 2018). Intramuscular injection in the deltoid produces blood levels ~ 28% higher than those produced with gluteal injection. The 3-month formulation of paliperidone palmitate has an extended apparent elimination half-life that permits this longer dosing interval. Risperidone is 90% plasma protein bound, whereas paliperidone is 74% plasma protein bound (Borison *et al.* 1994). The absolute bioavailability of risperidone is about 100%; that of extended-release paliperidone is about 28%. Paliperidone may achieve lower concentrations in the brain because of its higher affinity for the extruding P-glycoprotein transporter, which limits the amount of drug crossing the blood-brain barrier (de Leon *et al.* 2010).

Risperidone is metabolized by hydroxylation of the tetrahydro-pyrido-pyrimidinone ring at the seven and nine positions and by oxidative *N*-dealkylation (Mannens *et al.* 1993). The most important metabolite, 9-hydroxyrisperidone (paliperidone), accounts for up to 31% of the dose excreted in the urine. Because hydroxylation of risperidone is catalyzed by cytochrome P450 (CYP) 2D6, the half-life of the parent compound varies according to the relative activity of this enzyme. In extensive metabolizers, which include about 90% of white individuals and as many as 99% of Asian individuals, the half-life of risperidone is approximately 3 hours. Approximately 60% of paliperidone is excreted unchanged in the urine, and the remainder is metabolized by at least four different pathways (dealkylation, hydroxylation, dehydrogenation, and benzisoxazole scission), none of which accounts for more than 10% of the total. The terminal half-life of 9-hydroxyrisperidone (and of extended-release paliperidone) is 23 hours. Poor metabolizers metabolize risperidone primarily via oxidative pathways; the half-life may exceed 20 hours. In extensive metabolizers, radioactivity from ^{14}C-labeled risperidone is not detectable in plasma 24 hours after a single dose, whereas 9-hydroxyrisperidone accounts for 70%-80% of radioactivity. In poor metabolizers, risperidone is primarily responsible for radioactivity after 24 hours. In the U.S. multicenter registration trial, the correlations between risperidone dose and serum risperidone and 9-hydroxyrisperidone concentrations were 0.59 and 0.88, respectively (Anderson *et al.* 1993). Because of paliperidone's longer half-life, its serum concentrations at steady state are approximately 5 to 10 times higher than risperidone concentrations in CYP2D6 extensive metabolizers treated with risperidone (de Leon *et al.* 2010). However, in CYP2D6 poor metabolizers and patients concurrently taking CYP2D6 inhibitors, risperidone concentrations increase progressively according to reduced CYP2D6 activity (Kneller *et al.* 2020). The ratio of risperidone to paliperidone concentration is typically more than four times higher in poor metabolizers than in extensive metabolizers (Zhang *et al.* 2020).

Mechanism of Action

As previously discussed, risperidone was developed specifically to exploit the apparent pharmacological advantages of combining 5-HT$_2$ receptor antagonism with D$_2$ receptor blockade. Selective 5-HT$_{2A}$ receptor antagonists administered alone have demonstrated activity in several animal models suggestive of antipsychotic effect, including blockade of both amphetamine-and phencyclidine (PCP)-induced locomotor activity

(Schmidt *et al.* 1995). Dizocilpine-induced disruption of prepulse inhibition is also blocked by 5-HT$_{2A}$ receptor antagonists, suggesting that sensory gating deficits characteristic of schizophrenia and perhaps resulting from glutamatergic dysregulation might also benefit from the 5-HT$_2$ receptor antagonism of risperidone (Varty *et al.* 1999). The disruption of prepulse inhibition by dizocilpine (MK-801, a noncompetitive *N*-methyl-D-aspartate [NMDA] receptor antagonist) is attenuated by SGAs but not by first-generation D$_2$ receptor blockers (Geyer *et al.* 1990). From a study in which the selective 5-HT$_{2A}$ receptor antagonist M100907 was added to low-dose raclopride (a selective D$_2$ receptor blocker), Wadenberg *et al.* (1998) concluded that 5-HT$_{2A}$ antagonism facilitates D$_2$ receptor antagonist blockade of conditioned avoidance, another behavioral model associated with antipsychotic efficacy, but does not block conditioned avoidance when administered alone.

One mechanism by which risperidone, paliperidone, and similar atypical agents might increase efficacy for negative symptoms and cognitive deficits and reduce risk for EPS is via 5-HT$_{2A}$ receptor modulation of dopamine neuronal firing and cortical dopamine release. Prefrontal dopaminergic hypoactivity has been postulated to underlie negative symptoms and cognitive deficits in schizophrenia (Goff and Evins 1998); both clozapine and ritanserin have been shown to increase dopamine release in the prefrontal cortex, whereas haloperidol does not (Busatto and Kerwin 1997). After 21 days of administration, risperidone, but not haloperidol, continued to increase dopamine turnover in the dorsal striatum and prefrontal cortex (Stathis *et al.* 1996). Ritanserin has been shown to increase midbrain dopamine cell firing by blocking a tonic inhibitory serotonin input (Ugedo *et al.* 1989). Ritanserin also normalized ventral tegmental dopamine neuron firing patterns in rats after hypofrontality was induced by experimental cooling of the frontal cortex (Svensson *et al.* 1989).

Svensson *et al.* (1995) performed a series of elegant studies examining the impact of atypical antipsychotics on ventral tegmental dopamine firing patterns disrupted by glutamatergic NMDA receptor antagonists. In healthy human subjects, administration of the NMDA antagonist ketamine is widely regarded as a promising model for the development of several clinical aspects of schizophrenia, including psychosis, negative symptoms, and cognitive deficits (Goff and Coyle 2001; Krystal *et al.* 1994). In rats, administration of the NMDA channel blocker dizocilpine or PCP increased burst firing of ventral tegmental dopamine neurons predominantly projecting to limbic structures but reduced firing of mesocortical tract dopamine neurons and disrupted firing patterns. Administration of ritanserin or clozapine preferentially increased firing of dopamine neurons with cortical projections, and when added to a D_2 blocker, ritanserin increased dopamine release in prefrontal cortex. In addition to modulating ventral tegmental dopamine neuron firing, risperidone blocks 5-HT_2 receptors on inhibitory GABAergic interneurons, which could also influence activity of cortical pyramidal neurons that are regulated by these local inhibitory circuits (Gellman and Aghajanian 1994).

In placebo-controlled clinical trials, 5-HT_2 receptor antagonists have shown efficacy in reducing antipsychotic-induced parkinsonism and akathisia (Duinkerke *et al.* 1993; Poyurovsky *et al.* 1999). This effect may reflect 5-HT_{2A} antagonist effects on nigrostriatal dopamine release. When combined with haloperidol, selective 5-HT_2 receptor antagonists increase dopamine metabolism in the striatum and prevent an increase in D_2 receptor density, thereby possibly reducing the effects of D_2 receptor blockade and dopamine supersensitivity (Saller *et al.* 1990). These agents do not affect dopamine metabolism in the absence of D_2 blockade.

The relative importance of 5-HT_2 receptor antagonist activity in producing atypical characteristics is the subject of debate. Most SGAs (with the exception of partial D_2 agonists) have dissociation constants for the D_2 receptor that are larger than the dissociation constant of dopamine (Carboni *et al.* 2012; Kapur and Seeman 2001; Seeman 2002). This "loose binding" to the D_2 receptor may allow displacement by endogenous dopamine and may reduce the risks of EPS and hyperprolactinemia. Risperidone and paliperidone are "tightly bound" to the D_2 receptor, with a dissociation constant smaller than that of dopamine (Kozielska *et al.* 2012; Seeman

2002). A model for atypical antipsychotic mechanisms that emphasizes D_2 dissociation constants would predict that the apparent atypicality of risperidone, compared with that of haloperidol, reflects the reduced D_2 receptor occupancy achieved by more favorable dosing rather than the intrinsic pharmacological characteristics of risperidone. According to some binding data, a comparable clinical dosage of haloperidol would be approximately 4 mg/day, rather than 20 mg/day as used in the North American multicenter registration trial (Kapur *et al.* 1999). Consistent with this view, benefits of risperidone for negative symptoms and EPS were less apparent when compared with lower dosages of haloperidol or with lower-potency FGAs (see "Indications and Efficacy" section later in this chapter) than when compared with high-dose haloperidol (20 mg/day).

An additional mechanism that may possibly contribute to the increased efficacy of risperidone and paliperidone is their a-adrenergic receptor antagonism. In a placebo-controlled augmentation trial, Litman *et al.* (1996) demonstrated significant improvement in psychosis and negative symptoms with the a_2-adrenergic receptor antagonist idazoxan when it was added to FGAs. Idazoxan has been shown to increase dopamine levels in the rat medial prefrontal cortex (Hertel *et al.* 1999). In aged rats (Haapalinna *et al.* 2000) and in patients with frontal dementias (Coull *et al.* 1996), a_2-adrenergic receptor blockers have also been reported to improve cognitive functioning. Svensson *et al.* (1995) found that prazosin, an a_1 receptor antagonist, inhibited both the behavioral activation and the increase in mesolimbic dopamine release produced by PCP or MK-801.

In summary, risperidone and paliperidone possess at least two mechanisms that may confer atypical characteristics. 5-HT_{2A} receptor antagonism partially protects against D_2 antagonist-induced neurological side effects and may improve negative symptoms and cognitive functioning via modulation of mesocortical dopamine activity. In addition, blockade of adrenoceptors may further increase prefrontal cortical activity and could increase antipsychotic efficacy by modulating mesolimbic dopamine activity. Unlike other SGA agents, risperidone and paliperidone do not differ from FGAs in their dissociation constant for the D_2 receptor; this feature perhaps accounts for the risk of EPS at high dosages, as well as their greater propensity to cause hyperprolactinemia.

Indications and Efficacy

Risperidone is approved by the FDA for the treatment of schizophrenia, bipolar mania, and irritability associated with autism. In August 2007, the indication for schizophrenia was extended to include adolescents ages 13-17 years, and the bipolar mania indication was extended to include children 10-17 years of age. The risperidone microsphere formulation (Consta long-acting injectable [LAI]) is approved for the treatment of schizophrenia and bipolar I disorder. Extended-release oral paliperidone (Invega) is approved for the treatment of schizophrenia and schizoaffective disorder, LAI paliperidone palmitate (Sustenna) is approved for the treatment of schizophrenia and schizoaffective disorder, and PP3M (Invega Trinza) is approved for the treatment of schizophrenia.

Schizophrenia

Clinical Trial Results for Risperidone

Eight-week trials. In the two North American registration trials (Chouinard *et al.* 1993; Marder and Meibach 1994), a total of 513 patients with chronic schizophrenia were randomly assigned to an 8-week double-blind, fixed-dose, placebo-controlled

comparison of risperidone (2, 6, 10, or 16 mg/day) versus haloperidol (20 mg/day). Risperidone dosages of 6, 10, and 16 mg/day produced significantly greater reductions, as compared with haloperidol, in each of the five domains of the Positive and Negative Syndrome Scale (PANSS), derived by principal component analysis (Marder *et al.* 1997), and significantly higher response rates, defined as a 20% reduction in the PANSS total score. Effect sizes representing the difference in change scores between risperidone (6 mg/day) and haloperidol, although statistically significant, were uniformly small by Cohen's classification system (Cohen 1988): negative symptoms 0.31, positive symptoms 0.26, disorganized thoughts 0.22, uncontrolled hostility/excitement 0.29, and anxiety/depression 0.30 (Table 29-2). Severity of EPS was greater with haloperidol than with risperidone; further statistical analysis suggested that differences in EPS rates did not significantly influence the differences in PANSS subscale ratings (Marder *et al.* 1997). In fact, risperidone 10 mg/day and 16 mg/day produced improvements in negative symptoms equivalent to those seen with risperidone 6 mg/day, despite increased EPS at the higher dosages of risperidone.

TABLE 29-2. Effect sizes on PANSS symptom dimensions: North American trials (*N* = 513)

	Adjusted mean change scores			Risperidone 6 mg/day	
	Placebo	**Risperidone 6 mg/day**	**Haloperidol 20 mg/day**	**Effect size vs. placebo**	**Effect size vs. haloperidol**
PANSS total	[?] 3.8	[?] 18.6	[?] 5.1	0.53	0.31
Negative	0.2	[?] 3.4	[?] 0.1	0.27	0.26
Positive	0.9	[?] 5.7	[?] 2.3	0.48	0.22
Disorganized thought	0.1	[?] 4.6	[?] 0.2	0.43	0.24
Hostility/excitement	0.2	[?] 2.5	[?] 0.1	0.47	0.29

Source. Adapted from Marder *et al.* 1997.

In a comparison of risperidone (1, 4, 8, 12, and 16 mg/day) and haloperidol (10 mg/day) in a large 8-week European trial involving 1,362 subjects with schizophrenia (Peuskens and Risperidone Study Group 1995), PANSS subscale change scores among risperidone-treated subjects indicated a preferential response to daily dosages of 4 mg and 8 mg. However, neither the risperidone group taken as a whole nor individual risperidone dosages achieved significantly better outcomes than haloperidol (10 mg/day) on any measure except for EPS, suggesting that the clinical superiority of risperidone over haloperidol in previous studies may have resulted from excessively high dosing of the comparator.

CATIE. In the National Institute of Mental Health-funded Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE; Stroup *et al.* 2003), 1,432 patients with

chronic schizophrenia were randomly assigned to double-blind, flexibly dosed treatment for 18 months with risperidone, olanzapine, quetiapine, ziprasidone, or the FGA comparator perphenazine. Clinicians could adjust the dosage of each drug by prescribing 1-4 capsules daily; risperidone capsules contained 1.5 mg, and the mean daily dosage administered in the study was 3.9 mg. Based on the primary outcome measure, time to all-cause discontinuation, risperidone was less effective than olanzapine (mean dosage 20 mg/day) and comparable in effectiveness to perphenazine, quetiapine, and ziprasidone (Lieberman *et al.* 2005). Although differences in rates of dropout due to intolerance did not reach statistical significance, risperidone consistently was the best-tolerated drug, particularly for subjects who had discontinued their first assigned drug due to intolerance.

Maintenance treatment. Csernansky *et al.* (2002) randomly assigned 365 patients with stable schizophrenia or schizoaffective disorder to clinician-determined flexible dosing with risperidone or haloperidol for a minimum of 1 year. Kaplan-Meier estimates of the risk of relapse at the end of the study were 34% with risperidone and 60% with haloperidol, a highly significant difference (P = 0.001). The LAI risperidone microsphere formulation (Consta) at fixed dosages of 25 mg, 50 mg, and 75 mg administered biweekly was superior in efficacy to placebo in a 12-week trial (Kane *et al.* 2003), but the 75-mg biweekly dosage was not developed further due to a higher rate of EPS. In a 52-week maintenance study comparing fixed doses of risperidone microspheres administered every 2 weeks, the 25-mg dosage was associated with a relapse rate of 21.6%, and the 50-mg dosage was associated with a 14.9% relapse rate ($P = 0.06$) (Simpson *et al.* 2006). Comparisons of risperidone microspheres against oral SGAs have failed to demonstrate greater benefit with the LAI formulation in randomized trials. In 12-month randomized trials, the efficacy of risperidone microspheres was similar to that of oral risperidone ($n = 50$ [Bai *et al.* 2007]), oral olanzapine ($n = 377$ [Keks *et al.* 2007]), or clinician's choice of an oral antipsychotic other than clozapine ($n = 369$ [Rosenheck *et al.* 2011]). By contrast, a nationwide cohort study using national databases in Norway found risperidone microspheres to be more effective in preventing readmission after a first hospitalization compared with oral risperidone and other oral antipsychotics, with the exception of olanzapine and clozapine (Tiihonen *et al.* 2011). In a subsequent study involving more than 29,000 patients with schizophrenia in Sweden, paliperidone palmitate was the most effective of all studied medications in preventing rehospitalization (Tiihonen *et al.* 2017). Because antipsychotic treatments in these naturalistic studies were not randomized, conclusions are limited; nonetheless, the advantage found with depot formulations may reflect performance under typical clinical conditions.

Cognitive functioning in schizophrenia. Several early studies suggested that risperidone might better improve cognitive functioning, particularly verbal working memory, compared with haloperidol (Green *et al.* 1997; Harvey *et al.* 2005). A large double-blind trial that examined cognitive effects in 414 chronic schizophrenia patients treated for 52 weeks with risperidone (mean dosage 5.2 mg/day), olanzapine (12.3 mg/day), and haloperidol (8.2 mg/day) found no difference between treatments on the composite cognitive score, although risperidone and olanzapine were superior to haloperidol in a secondary analysis of completers (Keefe *et al.* 2006). When compared with low-dose haloperidol (mean dosage 5 mg/day), no cognitive advantage was found for risperidone (Green *et al.* 2002). In addition, in the CATIE, neither risperidone nor any other SGA demonstrated cognitive benefit compared with the FGA agent perphenazine (Keefe *et al.* 2007). A study in medication-naive patients found similar overall cognitive improvement with risperidone and olanzapine (Cuesta *et al.* 2009); however, another study of risperidone in medication-naive patients reported subsequent impairments of spatial working memory (Reilly *et al.* 2006) and procedural memory (Harris *et al.* 2009).

First-episode and treatment-refractory schizophrenia. Risperidone has been found to be well tolerated and effective for subgroups of patients with schizophrenia, including first-episode patients and older adults. In a 4-month double-blind trial comparing risperidone (mean dosage 3.9 mg/day) and olanzapine (mean dosage 11.8 mg/day) in 112 first-episode patients, both treatments were well tolerated, with an overall completion rate of 72% (Robinson *et al.* 2006). Response rates did not differ significantly between risperidone (54%) and olanzapine (44%), although patients who responded to risperidone were significantly more likely to retain their response. A similar study of 198 first-episode patients found no significant difference in response rates between risperidone (57%) and aripiprazole (63%) (Robinson *et al.* 2015). A 12-month double-blind trial comparing oral risperidone with LAI risperidone in 86 patients with recent-onset schizophrenia showed significantly lower relapse rates in the patients receiving the depot formulation (Subotnik *et al.* 2015). However, another randomized controlled trial of 85 first-episode patients found oral SGAs and LAI risperidone to be equally effective and to have similar safety profiles (Malla *et al.* 2016). Further studies with larger samples are probably necessary before treatment with LAI risperidone following a first episode of schizophrenia can be confidently recommended, although these findings indicate that it is a safe and effective option.

Experience with patients with treatment-resistant schizophrenia has been less consistent. In the U.S. multicenter registration study, Marder and Meibach (1994) found that patients who were presumed to have failed to respond to FGAs, on the basis of a history of hospitalization for at least 6 months before study entry, did not respond to haloperidol (20 mg/day) but did display significant response to risperidone (6 mg/day and 16 mg/day) compared with placebo. Wirshing *et al.* (1999) reported significant improvement with risperidone (6 mg/day) compared with haloperidol (15 mg/day) during a 4-week fixed-dose trial of 67 patients with schizophrenia and a history of treatment resistance. In contrast, Volavka *et al.* (2002) found no difference between high-dose risperidone (8-16 mg/day) and haloperidol (10-20 mg/day) in patients established by history to be treatment resistant to FGAs. In the CATIE, risperidone was more effective than quetiapine but did not differ from olanzapine and ziprasidone in patients who discontinued their first-assigned SGA medication due to lack of efficacy (Stroup *et al.* 2006). In contrast, patients who discontinued perphenazine (for any reason) subsequently did better on quetiapine or olanzapine than they did on risperidone (Stroup *et al.* 2007). Two meta-analyses comparing FGAs and SGAs suggested an advantage for risperidone over older drugs (Davis *et al.* 2003; Leucht *et al.* 2009), and a recent network meta-analysis broadly confirmed this suggestion (Leucht *et al.* 2013).

Clinical Trial Results for Paliperidone

In a 6-week trial of acutely ill schizophrenia patients, extended-release paliperidone (Invega) at dosages of 6, 9, and 12 mg/day was more effective than placebo (Kane et al. 2007), and in a flexibly dosed trial (9-15 mg/day), extended-release paliperidone significantly reduced relapse compared with placebo (Kramer *et al.* 2007). Combined results from three placebo-controlled trials involving 1,326 acutely ill patients with schizophrenia found significant improvement with paliperidone across a daily dosage range of 3-15 mg (Meltzer *et al.* 2008). Three studies compared paliperidone with olanzapine 10 mg/day and found no difference in efficacy, but paliperidone was associated with more movement disorders and less weight gain (Nussbaum and Stroup 2008). The network meta-analysis by Huhn *et al.* (2019) concluded that paliperidone was significantly less effective than clozapine but not risperidone, with risperidone and paliperidone displaying similar relationships to other antipsychotics.

LAI paliperidone palmitate administered every 4 weeks has been demonstrated to be more effective than placebo (Hough *et al.* 2010; Kramer *et al.* 2010; Nasrallah *et al.* 2010; Takahashi *et al.* 2013) and to be similar in efficacy to risperidone microspheres administered every 2 weeks (Pandina *et al.* 2011). The latter finding was not replicated in another study (Fleischhacker *et al.* 2012), although paliperidone palmitate dosing was suboptimal. A randomized clinical trial comparing LAI paliperidone palmitate with depot haloperidol administered in a matched loading-dose schedule (McEvoy *et al.* 2014) showed that the two drugs were equally effective in preventing relapse.

A Phase III clinical trial of PP3M (Invega Trinza) versus placebo was terminated early after the interim analysis clearly demonstrated the superior efficacy of PP3M (hazard ratio 3.45; 95% CI: 1.73-6.88; $P < 0.001$) (Berwaerts *et al.* 2015).

A second Phase III randomized, double-blind noninferiority study (N = 1,016) comparing PP3M with paliperidone palmitate 1-month formulation found no differences in efficacy, relapse rates, or side-effect profiles between the two formulations (Savitz *et al.* 2016).

Bipolar Disorder and Treatment-Resistant Major Depressive Disorder

Six controlled trials of 3-4 weeks' duration that included a total of 1,343 patients have examined the efficacy of risperidone as monotherapy or in combination with a mood stabilizer for the acute treatment of bipolar mania (Rendell *et al.* 2006). As monotherapy and in combination, risperidone was more effective than placebo and similar in efficacy to haloperidol but produced more weight gain and fewer EPS (Rendell *et al.* 2006). In a placebo-controlled trial of open-label risperidone LAI microspheres in the maintenance treatment of bipolar I disorder, patients (n = 303) with manic or mixed episodes who maintained response during a preceding 26-week period of LAI risperidone after an initial 3-week period of oral risperidone were randomly allocated to placebo injections or continued treatment with LAI risperidone for up to 24 months. A switch to placebo injections significantly shortened the time to recurrence of manic episodes but not depressive episodes (Quiroz *et al.* 2010).

Risperidone 1-2 mg/day was evaluated as an adjunct to antidepressant therapy in a 4-week placebo-controlled trial in 174 individuals with antidepressant-resistant major depressive disorder recruited from 19 primary care and psychiatric centers (Mahmoud *et al.* 2007). Risperidone produced significantly lowered ratings of depressive symptoms compared with placebo. Remission rates were 25% with risperidone versus

11% with placebo ($P = 0.004$). Risperidone was well tolerated, with an 81% study completion rate (vs. 88% with placebo).

Autism Spectrum Disorder and Intellectual Developmental Disorder

Risperidone also was studied in a large 8-week placebo-controlled trial of 101 children and adolescents (ages 5-17 years) with DSM-IV (American Psychiatric Association 1994)-defined autistic disorder accompanied by severe tantrums, aggression, or self-injurious behavior (McCracken *et al.* 2002). Flexible dosing with risperidone (range 0.5-3.5 mg/day; mean dosage 1.2 mg/day) resulted in a mean reduction of 57% in irritability, compared with a decrease of 14% in the placebo group, and the response rate was 69% with risperidone and 12% with placebo. In a study of 32 children (ages 5-17 years) with DSM-IV autistic disorder who were treated for 4 months with open-label risperidone (mean dosage 2 mg/day), those who continued treatment with risperidone during the second study arm, an 8-week double-blind substitution trial, had much lower relapse rates compared with patients who were switched to placebo (Research Units on Pediatric Psychopharmacology Autism Network 2005). Risperidone at a mean dosage of 2 mg/day was also found to be more effective than placebo in a study of 31 adults with DSM-IV autistic disorder or pervasive developmental disorder not otherwise specified (McDougle *et al.* 1998). In these studies, risperidone improved irritability and restricted, repetitive, and stereotyped behavioral problems associated with autism but was not effective for social or language deficits (McDougle *et al.* 2005). Risperidone at a dosage of 0.02-0.06 mg/kg was found to be well tolerated and effective for disruptive behaviors in children with low intelligence (IQ between 36 and 84) in a 6-week placebo-controlled trial (Aman *et al.* 2002); however, a randomized trial of risperidone, haloperidol, and placebo for nonpsychotic, aggressive adult patients with intellectual developmental disorder found no benefit for aggression with either active medication (Tyrer *et al.* 2008).

Other Disorders

Obsessive-Compulsive Disorder

A meta-analysis of antipsychotic augmentation in selective serotonin reuptake inhibitor-refractory OCD including three trials and 77 patients treated with risperidone found an advantage over placebo, with a standardized mean difference (SMD) of [?] 0.53 (Veale *et al.* 2014). Patients taking risperidone were 3.1 times more likely to respond to treatment than patients taking placebo, with a resultant number needed to treat (NNT) of 4.65. In contrast to haloperidol, treatment response was not more common with risperidone in the presence of comorbid tic disorder (McDougle *et al.* 2000).

Posttraumatic Stress Disorder

In a network meta-analysis involving 58 trials and 6,766 patients, risperidone was found to be more effective than placebo in the treatment of PTSD, with an SMD of [?] 0.53 (de Moraes Costa *et al.* 2020). A trial of adjunctive risperidone for patients with combat-related PTSD found improvements in overall sleep quality and a reduction in severity of nightmares (Krystal *et al.* 2016).

Generalized Anxiety Disorder

In a 4-week placebo-controlled add-on trial of low-dose risperidone in 417 patients with persistence of generalized anxiety disorder symptoms despite 8 weeks of anxiolytic therapy, no benefit from risperidone was found in the primary analysis; however, risperidone was associated with greater improvement in patients who had moderate or severe anxiety at baseline (Pandina *et al.* 2007). Risperidone was highly effective for OCD symptoms in a 6-week placebo-controlled trial of 36 adults prospectively confirmed to be nonresponsive to treatment with a selective serotonin reuptake inhibitor (McDougle *et al.* 2000). Symptoms of anxiety and depression also were more responsive to risperidone than to placebo. Fifty percent of risperidone-treated patients responded (mean dosage 2.2 mg/day), compared with none in the placebo group.

Alzheimer's Disease

In the CATIE-Alzheimer's Disease study, risperidone had the longest time to discontinuation due to lack of effectiveness (27 weeks) among the agents studied; comparison results were 22 weeks for olanzapine, 9 weeks for quetiapine, and 9 weeks for placebo (Schneider *et al.* 2006). However, because of poor tolerability, none of the three antipsychotics differed from placebo on time to all-cause discontinuation. Risperidone was associated with a small improvement (SMD [?] 0.26) on the Cohen-Mansfield Agitation Inventory in a network meta-analysis of 17 studies investigating SGA treatment of dementia (Yunusa *et al.* 2019), although the risk of cerebrovascular adverse events was 3.85 times that of placebo. Like all atypical antipsychotics, risperidone and paliperidone carry an FDA black box warning for risk of death in the treatment of older adults with dementia, following a 2005 meta-analysis of randomized controlled trials that showed a 54% increase in mortality over treatment with placebo (Schneider *et al.* 2006).

Side Effects and Toxicology

Risperidone shares class warnings with other SGAs in the United States, including the risks of tardive dyskinesia, neuroleptic malignant syndrome, and hyperglycemia and diabetes, as well as the risk of increased mortality in older adults with dementia-related psychosis. However, risperidone generally has been very well tolerated in clinical trials. In the U.S. multicenter trial reported by Marder and Meibach (1994), only headache and dizziness were significantly more common with risperidone 6 mg/day than with placebo, whereas the group receiving risperidone 16 mg/day treatment also reported more EPS and dyspepsia than did the group receiving placebo (Table 29-3). Fatigue, sedation, accommodation disturbances, orthostatic dizziness, palpitations or tachycardia, weight gain, diminished sexual desire, and erectile dysfunction displayed a statistically significant relationship to risperidone dosage, although most were not significantly elevated compared with placebo. In a flexible-dose relapse prevention study reported by Csernansky *et al.* (2002), no side effects were more common with risperidone compared with haloperidol, although risperidone produced significantly greater weight gain. In a flexibly dosed, placebo-controlled trial of risperidone for children with disruptive behavior, risperidone (mean dosage 1.2 mg/day) produced more somnolence, headache, vomiting, dyspepsia, weight gain, and prolactin elevation than did placebo; most side effects were rated mild to moderate and did not adversely affect compliance (Aman *et al.* 2002).

Metabolic Effects

Weight gain with risperidone is intermediate; that is, the degree of weight gain is between that associated with agents such as molindone, amisulpride, and ziprasidone, which appear to be relatively weight neutral, and that associated with agents such as clozapine, olanzapine, and low-potency phenothiazines (Rummel-Kluge *et al.* 2010; Sikich *et al.* 2008). In a meta-analysis of controlled trials, Allison *et al.* (1999), using a random effects model, estimated the mean weight gain at 10 weeks with risperidone to be 2.0 kg, compared with 0.5 kg with haloperidol, 3.5 kg with olanzapine, and 4.0 kg with clozapine. In the CATIE, in which risperidone had the lowest rate of discontinuation due to side effects, risperidone treatment was associated with a mean monthly weight gain of 0.4 lb, olanzapine with 2.0 lb, and quetiapine with 0.5 lb; by contrast, perphenazine and ziprasidone were associated with a mean monthly weight *loss* of 0.2 lb and 0.3 lb, respectively (Lieberman *et al.* 2005). Although determining the risk for hyperglycemia is complex, and results of studies have not been completely consistent, it appears that risperidone does not produce insulin resistance to the degree associated with olanzapine and clozapine (American Diabetes Association *et al.* 2004; Henderson *et al.* 2006; Lieberman *et al.* 2005). A meta-analysis of head-to-head comparisons of SGAs found that risperidone produced more cholesterol elevation than aripiprazole and ziprasidone and less elevation than olanzapine and quetiapine (Rummel-Kluge *et al.* 2010). Metabolic side effects in children tend to be more severe than those in adults; for example, in one study of pediatric patients younger than 20 years, risperidone produced a mean weight gain of 5.3 kg (11.7 lb) over the 12-week treatment period (Correll *et al.* 2009). Metabolic side effects with paliperidone appear to be similar to those with risperidone.

Extrapyramidal Side Effects

Significant reductions in EPS with risperidone compared with high-dose haloperidol were a consistent finding in the North American trials (Chouinard *et al.* 1993; Marder and Meibach 1994). Measurement of EPS in the placebo group was complicated because 25% of the subjects were receiving depot antipsychotics before enrollment. Risperidone produced significantly fewer parkinsonian side effects than did haloperidol (20 mg/day), based on several measures, including self-report, change scores on the Extrapyramidal Symptom Rating Scale, and use of anticholinergic medication. Patients receiving risperidone 2 mg/day and 6 mg/day did not differ from the group receiving placebo in mean ratings of parkinsonism and in the use of anticholinergic medication. Parkinsonism change scores were significantly correlated with risperidone dosage ($r = 0.94$); however, risperidone at 16 mg/day was associated with fewer parkinsonian side effects than was haloperidol. Dystonia occurred in six of the patients treated with risperidone (1.7%) and two of the patients treated with haloperidol (2.4%). Dystonia rates did not differ between treatment groups, and the rates did not exhibit a relationship to risperidone dosage.

In the large European multicenter trial, maximum ratings of parkinsonism, hyperkinesis, and dystonia were greater with haloperidol (10 mg/day) than with all dosages of risperidone (maximum of 12 mg/day), and anticholinergic dosing was accordingly higher in the group treated with haloperidol (Peuskens and Risperidone Study Group 1995). Similarly, in a flexible-dose comparison of risperidone (mean dosage 4.9 mg/day) and haloperidol (mean dosage 11.7 mg/day) for prevention of relapse, EPS rates and use of anticholinergic medication significantly favored the group taking risperidone (Csernansky *et al.* 2002). However, in a smaller double-blind, flexible-dose trial comparing risperidone (5-15 mg/day) and the moderate-potency FGA agent perphenazine (16-48 mg/day) in 107 patients, no difference in EPS rates was observed (Hoyberg *et al.* 1993), indicating that the potency of the comparator agent may in part determine the relative benefit of risperidone for EPS. Of interest, in a study of low-dose risperidone (mean dosage 1.2 mg/day) in children with behavioral disorders, ratings of EPS did not differ between risperidone and placebo (Aman *et al.* 2002). No differences in EPS ratings were found between any treatment groups in the CATIE (Lieberman *et al.* 2005), although discontinuation rates due to EPS significantly differed, with perphenazine producing the highest discontinuation rate (8%) and olanzapine (2%), risperidone (3%), and quetiapine (3%) producing the lowest.

The experience with tardive dyskinesia (TD) in individuals treated with risperidone has been promising. Jeste *et al.* (1999) randomly assigned 122 older adults to either low-dosage haloperidol (median daily dosage 1 mg) or risperidone (median daily dosage 1 mg). The very high rates of treatment-emergent TD typically found in older adults made this sample a sensitive assay for TD risk. After 9 months, rates of treatment-emergent TD were 30% with haloperidol versus less than 5% with risperidone. Risperidone was also noted to decrease dyskinetic movements compared with haloperidol in a Canadian multicenter trial reported by Chouinard *et al.* (1993), and it was associated with a treatment-emergent TD rate of 0.6%, compared with a rate of 2.7% with haloperidol, in a relapse prevention trial reported by Csernansky *et al.* (2002).

Hyperprolactinemia

Unlike other SGA agents, risperidone and paliperidone substantially increase serum prolactin levels. In the previously cited network meta-analysis by Huhn *et al.* (2019), paliperidone and risperidone were the two agents responsible for the greatest prolactin elevations, differing significantly from every treatment other than amisulpride. There is some evidence that prolactin levels may decrease over time (Eberhard *et al.* 2007; Findling *et al.* 2003-2Kleinberg *et al.* (1999) analyzed combined results from the North American and European multicenter registration trials, which included plasma prolactin concentrations from 841 patients and clinical ratings of symptoms associated with hyperprolactinemia from 1,884 patients. Mean prolactin levels significantly correlated with risperidone dosage; risperidone 6 mg/day produced elevations roughly comparable to those seen with haloperidol 20 mg/day and significantly higher than those seen with haloperidol 10 mg/day. The combined incidence of amenorrhea and galactorrhea in women, which varied between 8% and 12%, was similar for all dosages of risperidone and haloperidol (10 mg/day). Because symptom frequencies were available only for 14 women treated with placebo, comparisons with placebo were not informative. Sexual dysfunction or gynecomastia occurred in 15% of men treated with risperidone (4-6 mg/day), compared with 14% of men treated with haloperidol (10 mg/day) and 8% of men in the placebo group. Compared with placebo, ejaculatory dysfunction was significantly more common only in the group treated with risperidone (12-16 mg/day). Mean plasma prolactin levels were not significantly related to clinical side effects for either men or women. Decreased libido also did not differ between treatment groups and did not correlate with plasma prolactin levels. In the CATIE, prolactin levels increased by a mean of 15.4 ng/mL with risperidone, compared with a 0.4 ng/mL mean elevation with perphenazine and decreases of 4.5-9.3 ng/mL with the other SGAs (Lieberman *et al.* 2005). Despite having significantly higher serum prolactin concentrations, patients treated with risperidone did not report significantly higher rates of sexual dysfunction, gynecomastia, galactorrhea, or irregular menses.

Two reports of clinical trials with extended-release paliperidone have indicated low levels of prolactin-related side effects (1% and 4%) (Kane *et al.* 2007; Kramer *et al.* 2007). However, in the one publication that reported prolactin levels, substantial increases in mean plasma prolactin concentrations were observed (men: 17.4 ng/mL at baseline to 45.3 ng/mL at week 6; women: 38.0 ng/mL to 124.5 ng/mL) (Kane *et al.* 2007). A 13-week comparison of paliperidone palmitate with risperidone microspheres reported that paliperidone palmitate was associated with moderately higher elevations from baseline in prolactin levels compared with risperidone (women: 21.8 vs. 15.6 ng/mL; men: 9.4 vs. 6.0 ng/mL) (Pandina *et al.* 2011); however, another study found that the proportion of patients with abnormally elevated prolactin levels was higher in the group receiving LAI risperidone than in that receiving paliperidone palmitate (Fleischhacker *et al.* 2012). Two preliminary studies with risperidone found that plasma prolactin concentrations correlated with 9-hydroxyrisperidone (paliperidone) concentrations and not with risperidone concentrations (Melkersson 2006; Troost *et al.* 2007). The ratio of 9-hydroxyrisperidone levels to risperidone levels also correlated with prolactin concentration (Troost *et al.* 2007); in agreement with this finding, rapid metabolizers of CYP2D6 were found to have higher prolactin concentrations than poor metabolizers (Troost *et al.* 2007).

Cardiovascular Effects

Because of its high affinities for adrenoreceptors, risperidone would be expected to produce orthostatic hypotension. However, with a 3-to 7-day dosage escalation schedule, initial postural hypotension and tachycardia have been avoided in clinical trials, with only rare cases of hypotension and syncope reported (Chouinard *et al.* 1993; Marder and Meibach 1994). Risperidone has very modest effects on cardiac conduction. No significant prolongation of the QTc interval was detected at dosages of up to 25 mg/day in early safety trials, and no relationship between QTc interval and risperidone dosage was apparent (Mesotten *et al.* 1989). A mean QTc prolongation of 10 milliseconds, measured after peak absorption of risperidone (16 mg/day), was found in a study comparing SGAs and FGAs, according to data filed with the FDA by Pfizer Inc. (Harrigan *et al.* 2004). In a retrospective cohort study of Medicaid enrollees in Tennessee, risperidone was associated with a 2.9-fold increase in rate of sudden cardiac death, compared with a 1.61-fold increase with haloperidol and a 3.67-fold increase with clozapine (Ray *et al.* 2009).

High Dosage and Overdose

Mesotten *et al.* (1989) reported the results of a safety trial involving 17 inpatients with psychosis in which, after a washout of previous medication, risperidone was started at 10 mg/day, and the dosage was then increased weekly by 5 mg/day to a maximum of 25 mg/day. Despite extremely high dosages, sedation was the only prominent side effect. Although risperidone does not bind significantly to muscarinic cholinergic receptors, transient dry mouth, blurred vision, and urinary retention were observed in individual subjects. Palpitations occurred in two subjects. Heart rate significantly increased during the trial, and blood pressure slightly decreased; however, no cases of significant hypotension were reported. An endocrine battery, including plasma triiodothyronine, thyroid-stimulating hormone, growth hormone, prolactin, follicle-stimulating hormone, luteinizing hormone, and cortisol levels, was performed, and only prolactin was found to be affected.

Reported overdoses with risperidone have generally been benign, with moderate QT prolongation and no serious cardiac complications (Brown *et al.* 1993; Lo Vecchio *et al.* 1996).

Drug-Drug Interactions

Because CYP2D6 status affects the half-life of risperidone and the relative ratio of risperidone to 9-hydroxyrisperidone in plasma, the total serum concentration of the

"active moiety," or the sum of the concentrations of risperidone and 9-hydroxyrisperidone, may be significantly increased with addition of a CYP2D6 inhibitor (e.g., fluoxetine) in rapid metabolizers but not in poor metabolizers (Bondolfi *et al.* 2002; Spina *et al.* 2002). In one study of nine patients treated with risperidone, the addition of fluoxetine resulted in a 75% increase in blood levels of the active moiety (risperidone plus 9-hydroxyrisperidone); two patients developed parkinsonian side effects (Spina *et al.* 2002). Paliperidone plasma concentrations are not influenced by CYP2D6 status, nor are paliperidone plasma concentrations likely to be affected by drug-drug interactions. It has been hypothesized that the addition of a CYP2D6 inhibitor (e.g., fluoxetine) could decrease risperidone-induced prolactin elevation by increasing the ratio of risperidone to 9-hydroxyrisperidone (Troost *et al.* 2007), although this has not been rigorously tested.

Conclusion

Risperidone was the first antipsychotic agent developed specifically to exploit the clinical advantages of combined D_2 and $5\text{-}HT_{2A}$ receptor antagonism. a-Adrenergic antagonism additionally may contribute to the antipsychotic and potentially cognition-enhancing effects of risperidone. Risperidone's active metabolite, paliperidone, is pharmacologically quite similar to the parent drug and comprises roughly 80%-90% of the serum concentration of the active moiety (risperidone + paliperidone) in most patients treated with risperidone. Risperidone and paliperidone are generally quite well tolerated, producing moderate weight gain and mild sedation. Initial dosage titration is necessary to prevent orthostatic blood pressure changes and dizziness, although this may be less necessary with extended-release paliperidone. EPS are dose related and are typically less common with risperidone than with haloperidol but more common with risperidone than with other SGAs. Risperidone and paliperidone markedly elevate prolactin levels, although the relationship between plasma prolactin concentrations and clinical symptoms is complex. The efficacy of risperidone was initially established in comparison with high-dose haloperidol, against which it was significantly more effective for all five symptom clusters derived from the PANSS. However, the magnitude of difference in effect size was not large for individual symptom clusters. In the CATIE, risperidone (at a mean daily dosage of 3.9 mg) did not differ from perphenazine in rates of discontinuation due to lack of effectiveness but was less effective than olanzapine (Lieberman *et al.* 2005). The risperidone microsphere product was the first FDA-approved SGA long-acting intramuscular formulation, and paliperidone palmitate was the first SGA depot formulation that could be administered at an interval of every 4 weeks. PP3M is the first depot antipsychotic that can be administered on a quarterly schedule. Overall, risperidone and paliperidone are well-tolerated SGA agents with efficacy comparable to that of most other agents in their class.

CHAPTER 30

Aripiprazole and Brexpiprazole

Nikolajs K. Birze, M.D.
Chloe J. Yuan, M.D.
Erica C. Garcia-Pittman, M.D., FAPA, DFAAGP

In this chapter, we review the preclinical and clinical pharmacology of aripiprazole and brexpiprazole, two novel atypical (second-generation) antipsychotics.

History and Discovery

Aripiprazole is a dihydroquinolinone antipsychotic agent. Chemically, it is unrelated to phenothiazines, butyrophenones, or thienobenzodiazepines. Pharmacologically, it was the first antipsychotic to exhibit a novel mechanism of action, combining partial agonist activity at dopamine type 2 (D_2), dopamine type 3 (D_3), and serotonin type 1A (5-HT_{1A}) receptors with antagonist activity at serotonin type 2A (5-HT_{2A}) and D_2 receptors (Burris *et al.* 2002; Jordan *et al.* 2002). Aripiprazole represents a significant innovation, following the introduction of typical (first-generation) and atypical antipsychotics, in the pharmacology of therapeutic agents for psychotic disorders.

The development of aripiprazole was guided by prevailing hypotheses of the etiology of schizophrenia. The dopamine hypothesis (Seeman and Niznik 1990) proposes that abnormalities in dopaminergic neurotransmission in the brain cause the symptoms of schizophrenia and suggests that schizophrenia involves a biphasic disturbance in dopaminergic pathways (Davis *et al.* 1991; Pycock *et al.* 1980; Weinberger 1987). Underactivity of the mesocortical dopaminergic pathway leads to hypodopaminergic activity in the frontal cortex, whereas overactivity in the mesolimbic pathway causes increased dopaminergic neurotransmission. The latter is presumed to cause positive or psychotic symptoms, whereas the former is believed to underlie negative symptoms and cognitive impairment. Another influential hypothesis suggests that the activity of dopaminergic pathways is modulated by serotonergic neurons. In the striatum, serotonin (5-hydroxytryptamine; 5-HT) release inhibits dopamine, whereas in the frontal cortex 5-HT release has a modulatory effect on pyramidal neurons and can affect glutamate release.

Most typical and atypical antipsychotic agents behave as full D_2 receptor antagonists. Their actions in the mesolimbic pathway would therefore be expected to benefit patients with schizophrenia by reducing positive symptoms. However, D_2 receptor antagonism in the other dopaminergic pathways would be expected to cause unwanted side effects, including exacerbation of negative symptoms (mesocortical pathways), extrapyramidal side effects (EPS) and tardive dyskinesia (nigrostriatal tract), and hyperprolactinemia (tuberoinfundibular pathway).

The serotonin hypothesis may explain why the atypical agents, which have antagonist activity at 5-HT_{2A} receptors, are associated with fewer EPS and do not exacerbate (and, in fact, partially alleviate) negative symptoms and cognitive impairment (Leysen *et al.* 1993; Millan 2000; Rao and Moller 1994; Richelson 1999).

On the basis of aripiprazole's pharmacodynamic profile--partial agonist activity at both dopaminergic (D_2 [Burris *et al.* 2002]) and serotonergic (5-HT_{1A} [Jordan *et al.* 2002]) receptors and full antagonist activity at 5-HT_{2A} receptors (McQuade *et al.* 2002)--it was anticipated that aripiprazole treatment would be associated with a reduced burden of unwanted D_2 antagonist activity in the mesocortical, nigrostriatal, and tuberoinfundibular pathways.

Aripiprazole was initially discovered by scientists at Otsuka Pharmaceutical and was first FDA approved for the treatment of schizophrenia in November 2002. Aripiprazole obtained additional FDA indications for manic and mixed episodes associated with bipolar I disorder in 2004, adjunctive treatment of major depressive disorder (MDD) in 2007, irritability associated with autism in 2009, and Tourette's disorder in 2014 (Otsuka Pharmaceutical 2020a). In February 2013, the FDA approved a long-acting depot injectable formulation of aripiprazole for the treatment of schizophrenia. In 2018 this formulation was also approved by the FDA for monotherapy in maintenance treatment of bipolar I disorder (Otsuka Pharmaceutical 2020b). In October 2015, the FDA approved aripiprazole lauroxil, a second long-acting formulation of aripiprazole, for the treatment of schizophrenia (Alkermes 2021a).

Brexpiprazole was first synthesized by Otsuka Pharmaceutical and developed in collaboration with H. Lundbeck A/S with the goal of optimizing its intrinsic activity at D_2 receptors. The pharmacological profile of brexpiprazole is similar to that of aripiprazole, including combined partial agonist activity at D_2, D_3, and 5-HT_{1A} receptors with antagonist activity at 5-HT_{2A} and D_2 receptors. However, brexpiprazole has lower intrinsic activity at D_2 receptors, high-potency partial agonism at 5-HT_{1A} receptors, and stronger antagonism at 5-HT_{2A} receptors (Maeda *et al.* 2014b). Its reduced intrinsic activity at D_2 receptors and stronger antagonism at 5-HT_{2A} receptors relative to aripiprazole suggest a lower potential to induce D_2 partial agonist-mediated effects (i.e., akathisia, insomnia, nausea, and restlessness) and D_2 antagonist effects

(e.g., dystonias, tardive dyskinesia, and hyperprolactinemia) (Fleischhacker 2005; Maeda *et al.* 2014a). Brexpiprazole was approved by the FDA in 2015 for the treatment of schizophrenia and as an adjunctive therapy with antidepressants for the treatment of MDD (Otsuka Pharmaceutical 2023). In 2023, brexpiprazole received supplemental approval for the treatment of agitation associated with dementia due to Alzheimer's disease, becoming the first medication in the United States to have such an indication (U.S. Food and Drug Administration 2023).

Structure-Activity Relations and Pharmacological Profile

Aripiprazole

Aripiprazole--7-{4-(4-[2,3-dichlorophenyl]-1-piperazinyl)butoxy}-3,4-dihydrocarbostyril, a dihydroquinolinone (Figure 30-1)--exhibits potent partial agonist activity at D_2 (Burris *et al.* 2002) and 5-HT_{1A} (Jordan *et al.* 2002) receptors, together with potent antagonist activity at 5-HT_{2A} receptors. It also has high affinity for D_3 receptors; moderate affinity for dopamine type 4 (D_4), serotonin type 2C (5-HT_{2C}), serotonin type 7 (5-HT_7), a_1-adrenergic, and histamine type 1 (H_1) receptors and the serotonin transporter; and negligible affinity for cholinergic muscarinic receptors (Table 30-1). The active metabolite of aripiprazole, dehydroaripiprazole, exhibits a similar affinity at D_2 receptors and has not been shown to have a pharmacological profile that is clinically significantly different from that of the parent compound.

Brexpiprazole

Brexpiprazole--7-{4-[4-(1-benzothiophen-4-yl)piperazin-1-yl]butoxy}quinolin-2(1H)-one (Figure 30-2)--exhibits potent partial agonist properties at 5-HT$_{1A}$, D_2, and D_3 receptors. This is combined with potent antagonist activity at 5-HT$_{2A}$ receptors and a_{1B}/a_{2C} adrenoceptors. It also displays antagonistic properties at serotonin type 2B (5-HT_{2B}) and serotonin type 7A (5-HT_{7A}) receptors and moderate-potency antagonism at H_1 receptors. Brexpiprazole has negligible affinity for cholinergic muscarinic receptors (Table 30-2) (Maeda *et al.* 2014a; Otsuka Pharmaceutical 2023).

Pharmacokinetics and Disposition

Aripiprazole

Aripiprazole is available for oral administration as tablets in strengths of 2, 5, 10, 15, 20, and 30 mg. Aripiprazole orally disintegrating tablets are available in strengths of 10 and 15 mg, and an oral solution of 1 mg/mL is available. The effective dosage range is 10-30 mg/day for patients with schizophrenia and 15-30 mg/day for patients with bipolar I disorder. For adjunctive treatment of MDD and irritability associated with autism spectrum disorder, the recommended dosage range is 2-15 mg/day. For Tourette's disorder, body weight-based dosing of 2-10 mg/day for patients weighing less than 50 kg and 2-20 mg/day for patients weighing 50 kg or more is indicated.

Oral aripiprazole is available with an embedded ingestible event marker (Abilify MyCite), meant to track drug ingestion and monitor compliance (Otsuka Pharmaceutical 2017). The tablets have an embedded ingestible sensor that records that the medication was taken. The system works by sending a message from the tablet sensor to a wearable patch. The patch transmits the information to a mobile application so that patients can track the ingestion of their medication on their smart phone (U.S. Food and Drug Administration 2017). Patients can also permit their caregivers to access the information through a web-based portal. However, there are no head-to-head studies showing improved medication adherence with the use of the MyCite formulation (Cosgrove *et al.* 2019).

Of note, several aripiprazole formulations were withdrawn from the market by the manufacturer in 2015 for reasons unrelated to efficacy, safety, or tolerability. Unavailable formulations include the aripiprazole oral disintegrating tablet at the 20-mg and 30-mg strengths and the short-acting intramuscular injection.

Aripiprazole is taken once daily with or without food and is well absorbed after oral administration, with peak plasma concentrations occurring within 3-5 hours. Absolute oral bioavailability is 87%. In plasma, aripiprazole and its major metabolite, dehydroaripiprazole, are both more than 99% bound to proteins, primarily albumin. Aripiprazole is extensively distributed outside the vascular system, and studies in humans demonstrating dose-dependent occupancy of D_2 receptors have confirmed that aripiprazole penetrates the brain. Elimination half-lives for aripiprazole and dehydroaripiprazole are 75 hours and 94 hours, respectively (Otsuka Pharmaceutical 2020a).

The aripiprazole depot formulation consists of a lyophilized powder of unmodified aripiprazole that is reconstituted in water and injected into the gluteal or deltoid muscle (Otsuka Pharmaceutical 2020b). The product is available in 300-mg and 400-mg vials, and the effective dosage range is 300-400 mg once monthly. The median peak plasma concentration is reached after 5-7 days. It is recommended that oral aripiprazole supplementation (at 10-20 mg/day) or an alternative antipsychotic be continued for 2 weeks after the first administered injection of long-acting aripiprazole. The mean terminal half-lives of the 300-mg and 400-mg doses are 29.9 and 46.5 days, respectively. Steady-state plasma concentrations are attained after the fourth dose (Otsuka Pharmaceutical 2020b). The aripiprazole once-monthly intramuscular dose of 400 mg with supplemental oral aripiprazole 10 mg/day for the first 2 weeks produces a pharmacokinetic profile consistent with multiple daily dosing of aripiprazole 10-30 mg, with a maximum plasma concentration comparable to that of the 30 mg/day dosage and a minimum plasma concentration comparable to that of the 10 mg/day dosage (Mallikaarjun *et al.* 2013).

Aripiprazole lauroxil, a prodrug of aripiprazole, initially undergoes enzyme-mediated hydrolysis to *N*-hydroxymethyl aripiprazole and then undergoes water-mediated hydrolysis to aripiprazole, the active form. The effective dosage range of aripiprazole lauroxil is 441 mg or 662 mg administered monthly, 882 mg administered monthly or every 6 weeks, and 1,082 mg administered every 2 months. After a single intramuscular injection, aripiprazole appears in systemic circulation within 5-6 days. Aripiprazole lauroxil reaches steady state after four consecutive monthly injections. Mean terminal half-life ranges from 53.9 days to 57.2 days (Alkermes 2021a).

Aripiprazole lauroxil may be initiated in two ways, the first being administration of oral aripiprazole supplementation for 3 weeks after the first administered injection. The second way to initiate aripiprazole lauroxil is with the NanoCrystal Dispersion formulation, which is given as a one-time 675-mg injection in conjunction with one dose of oral aripiprazole 30 mg and the first dose of aripiprazole lauroxil (441, 662, 882, or 1,082 mg). An intramuscular injection of aripiprazole lauroxil, a 30-mg dose of oral aripiprazole, and a single 675-mg dose of aripiprazole lauroxil NanoCrystal Dispersion resulted in aripiprazole concentrations comparable to those from aripiprazole lauroxil treatment initiated with 21 days of oral aripiprazole (Alkermes 2021a, 2021b).

Aripiprazole is metabolized primarily in the liver. Two hepatic cytochrome P450 (CYP) enzymes, 2D6 and 3A4, catalyze its dehydrogenation to dehydroaripiprazole. The active metabolite accounts for 40% of drug exposure, but the predominant circulating moiety is the parent drug. Aripiprazole does not undergo direct glucuronidation and is not a substrate for the following CYP enzymes: 1A1, 1A2, 2A6, 2B6, 2C8, 2C9, 2C19, and 2E1. Interactions with inhibitors or inducers of these enzymes, or with chemicals related to cigarette smoke, are therefore unlikely to occur.

Brexpiprazole

Brexpiprazole is available for oral administration as tablets with strengths ranging from 0.25 to 4 mg. Ninety-five percent of the estimated maximum efficacy is obtained at a dosage of 3.36 mg/day (Leucht *et al.* 2020). The effective dosage range is 2-4 mg/day for treatment of schizophrenia, 1-3 mg/day for adjunctive treatment of MDD, and 2-3 mg/day for agitation associated with dementia due to Alzheimer's disease.

Brexpiprazole is taken once daily with or without food and is well absorbed after oral administration, with peak plasma concentrations occurring within 4 hours. Absolute oral bioavailability is 95%. Brexpiprazole is highly bound to serum albumin and a_1-acid glycoprotein (> 99%). Elimination half-lives for brexpiprazole and DM-3411, its major metabolite, are 91 hours and 86 hours, respectively (Otsuka Pharmaceutical 2023).

Brexpiprazole is metabolized primarily through the liver by CYP enzymes 2D6 and 3A4. At steady state (which is reached in 10-12 days), the inactive metabolite DM-3411 represents 23%-48% of brexpiprazole's area under the time-concentration curve in plasma (Otsuka Pharmaceutical 2023). Dosage adjustment (a maximum of 2 mg/day for major depressive disorder and of 3 mg/day for schizophrenia) is also recommended for patients with moderate to severe hepatic or renal impairment (Otsuka Pharmaceutical 2023).

Mechanism of Action

Aripiprazole and brexpiprazole both have partial agonist activity at D_2 receptors. The activity of aripiprazole and brexpiprazole at D_2 receptors has been studied in animal models of schizophrenia (Kikuchi *et al.* 1995; Maeda *et al.* 2014b). Hyperdopaminergic activity, seen in rats with repetitive stereotyped behavior induced by apomorphine, is inhibited by both aripiprazole and brexpiprazole (Kikuchi *et al.* 1995; Maeda *et al.* 2014a). These agents may therefore be expected to inhibit hyperdopaminergic activity in the mesolimbic pathway of patients with schizophrenia, thereby (like other available agents) exerting antipsychotic action against the positive symptoms of schizophrenia. On the other hand, in animal models of hypodopaminergic activity, such as the reserpinized rat, both aripiprazole and brexpiprazole have D_2 receptor agonist activity (Maeda *et al.* 2014b). Because aripiprazole and brexpiprazole may postsynaptically exert either D_2 antagonist activity under hyperdopaminergic conditions or D_2 agonist activity under hypodopaminergic conditions, they may be less likely than other antipsychotics to cause excessive D_2 receptor antagonism. In preclinical studies, brexpiprazole showed lower intrinsic activity at D_2 receptors, which suggests a reduced propensity to cause D_2 agonist-associated side effects such as nausea, insomnia, and akathisia (Maeda *et al.* 2014a, 2014b). It is possible that this lower activity may diminish the effects of excess D_2 receptor antagonism, including EPS. No comparative clinical trials of aripiprazole and brexpiprazole have yet been conducted.

Both aripiprazole and brexpiprazole may offer further therapeutic benefits through modulation of central serotonergic pathways. Preclinical studies demonstrated that aripiprazole and brexpiprazole have antagonist activity at 5-HT_{2A} receptors (Maeda *et al.* 2014b; McQuade *et al.* 2002), a characteristic that has been associated with reductions in EPS (Meltzer 1999) and in negative symptoms. In vitro studies also have shown that both aripiprazole and brexpiprazole have partial agonist activity at 5-HT_{1A} receptors (Jordan *et al.* 2002; Maeda *et al.* 2014b), a feature that has been associated with improvement in negative, cognitive, depressive, and anxiety symptoms (Millan 2000).

The side effects of nausea and vomiting may be explained by the dopamine agonist effects of aripiprazole and brexpiprazole, whereas orthostatic hypotension and mild

sedation or weight gain are probably related to these agents' antagonist activity at a_1-adrenergic and H_1 receptors, respectively.

Indications and Efficacy

Aripiprazole

In the United States, aripiprazole is approved by the FDA for treatment of schizophrenia in adults and in adolescents ages 13-17 years, acute treatment of manic or mixed episodes associated with bipolar I disorder as monotherapy and as an adjunct to lithium or valproate in adults and pediatric patients ages 10-17 years, maintenance treatment of manic or mixed episodes associated with bipolar I disorder as monotherapy and as an adjunct to lithium or valproate in adults, use as an adjunct to antidepressant treatment in adults with MDD who have had an inadequate response to antidepressant therapy, treatment of irritability associated with autism spectrum disorder in pediatric patients ages 6-17 years, and treatment of Tourette's disorder in pediatric patients ages 6-18 years. Aripiprazole is currently available in two formulations for long-acting injectable depot maintenance and relapse management of schizophrenia in adults. Aripiprazole long-acting depot injection is approved for maintenance monotherapy treatment of bipolar I disorder in adults. Additionally, a short-acting intramuscular aripiprazole injection is approved for the acute treatment of agitation associated with schizophrenia or bipolar disorder (manic or mixed) in adults; however, this formulation is no longer available.

Schizophrenia

Aripiprazole's efficacy in the treatment of an acute symptom relapse in schizophrenia was demonstrated in four short-term (4-week) double-blind, placebo-controlled studies. Among these was a pivotal Phase III parallel-group multicenter study with four treatment arms comparing aripiprazole (15 or 30 mg/day) with placebo (Kane *et al.* 2002). Aripiprazole at either dosage produced statistically significant improvements from baseline on Positive and Negative Syndrome Scale (PANSS) and Clinical Global Impression (CGI) Scale scores by week 2. This trial suggested that at daily dosages of 15 mg and 30 mg, aripiprazole provides effective symptom control for patients experiencing an acute exacerbation of schizophrenia symptoms.

In another short-term multicenter Phase III study involving acute symptom relapse in schizophrenia or schizoaffective disorder (Potkin *et al.* 2003), patients were randomly assigned to receive aripiprazole 20 mg/day, aripiprazole 30 mg/day, risperidone 6 mg/day, or placebo for 4 weeks. Compared with placebo, aripiprazole (at both dosages) and risperidone produced statistically significant improvements in scores on standard scales designed to measure antipsychotic efficacy.

The antipsychotic efficacy of aripiprazole in acute symptom relapse in schizophrenia was also demonstrated in two Phase II dose-ranging studies. Patients were randomly assigned to receive aripiprazole 2, 10, or 30 mg/day or haloperidol 10 mg/day (Daniel *et al.* 2000). All three dosages of aripiprazole produced improvements from baseline on efficacy measures, and the 30 mg/day dosage produced statistically significantly greater improvement compared with placebo on all illness scores. Similarly, in a Phase II dosage titration study, aripiprazole 5-30 mg/day was superior to placebo in improving Brief Psychiatric Rating Scale (BPRS) Total, BPRS Core, CGI-Severity, and PANSS-Total scores (Petrie *et al.* 1997).

Results from the three 4-week fixed-dosage studies discussed above (Daniel *et al.* 2000; Kane *et al.* 2002; Petrie *et al.* 1997) were pooled for analysis with those from a 6-week placebo-controlled, fixed-dosage study of aripiprazole at 10, 15, or 20 mg/day (Lieberman *et al.* 2002). The pooled analysis, involving 898 patients randomly assigned to receive aripiprazole, showed that at all investigated dosages greater than 2 mg/day, aripiprazole exhibited antipsychotic efficacy superior to that of placebo. Onset of effect was rapid, with improvement in psychometric scores detectable within 1 week of starting treatment. These pooled efficacy results demonstrate that dosages of 10-30 mg/day represent an effective therapeutic range for aripiprazole treatment.

Two long-term double-blind, randomized controlled multicenter trials yielded further confirmation of aripiprazole's efficacy. A 26-week placebo-controlled study of patients with chronic stable schizophrenia investigated the efficacy of aripiprazole 15 mg/day in relapse prevention (Pigott *et al.* 2003). Aripiprazole treatment significantly increased the time to relapse and resulted in significantly fewer relapses compared with placebo (34% vs. 57%). From week 6 of therapy, PANSS-Total and PANSS-Positive subscale scores showed significantly greater improvement with aripiprazole than with placebo.

In a 52-week study (Kasper *et al.* 2003), patients with schizophrenia who were experiencing an acute symptom relapse were randomly assigned to receive aripiprazole 30 mg/day or haloperidol 10 mg/day. Significantly more aripiprazole-treated patients than haloperidol-treated patients were still taking the medication and responding to treatment at weeks 8, 26, and 52. Both treatments produced sustained improvements from baseline on PANSS-Total and PANSS-Positive subscale scores. However, aripiprazole produced significantly greater improvements in negative and depressive symptoms at weeks 26 and 52 and was associated with significantly lower scores on all EPS assessments compared with haloperidol.

The efficacy of aripiprazole monotherapy in antipsychotic-resistant schizophrenia was evaluated in a 6-week double-blind, randomized trial in patients whose symptoms had not improved during a prospective 4-to 6-week open trial with either olanzapine or risperidone (Kane *et al.* 2007). Subjects were randomly assigned to receive aripiprazole (15-30 mg/day) or perphenazine (8-64 mg/day). After 6 weeks, there was no statistical difference between the two groups on efficacy measures.

A meta-analysis of 14 studies showed no difference in efficacy or safety and tolerability between aripiprazole and brexpiprazole in the treatment of acute schizophrenia in adults (Kishi *et al.* 2020).

The efficacy of aripiprazole in the treatment of schizophrenia in pediatric patients (ages 13-17 years) was evaluated in a 6-week placebo-controlled outpatient trial comparing two fixed daily dosages of aripiprazole (10 mg or 30 mg) with placebo (Findling *et al.* 2008). Both aripiprazole dosages demonstrated statistically significant differences from placebo in reductions in PANSS-Total score; the 30 mg/day dosage was not shown to be more efficacious than the 10 mg/day dosage.

In a 6-week randomized, double-blind dose comparison study, pediatric patients (ages 13-17 years) with schizophrenia were randomly assigned to receive aripiprazole 2, 6-12, or 24-30 mg/day followed by a 52-week open-label extension (Matsumoto *et al.* 2018). Changes in the PANSS-Total score from baseline to endpoint were [?] 19.6 for 2 mg/day, [?] 16.5 for 6-12 mg/day, and [?] 21.6 for 24-30 mg/day. The PANSS-Total score decreased by 7.9 from the open-label extension baseline to week 52.

Efficacy and tolerability of aripiprazole in the maintenance treatment of schizophrenia in pediatric patients (ages 13-17 years) was evaluated in a 52-week double-blind, placebo-controlled, randomized withdrawal design trial (Correll *et al.* 2017). Patients were stabilized on 10-30 mg of oral aripiprazole and then randomly assigned 2:1 to continuation of oral aripiprazole or to placebo. Treatment with aripiprazole was associated with a significantly longer time to exacerbation of psychotic symptoms or relapse compared with placebo ($P = 0.016$).

Two studies have investigated the efficacy of the aripiprazole long-acting depot injection in the prevention of relapse in schizophrenia. In the first investigation, a randomized, placebo-controlled, 52-week multicenter maintenance study, participants requiring long-term treatment with an antipsychotic entered an oral aripiprazole stabilization phase followed by an intramuscular depot conversion and stabilization phase. Patients meeting stabilization criteria for 12 consecutive weeks were then randomly assigned to receive aripiprazole 400 mg long-acting depot or placebo depot for the 52-week double-blind maintenance phase of the study. The primary outcome measure was time to relapse, defined as meeting any or all of the following criteria at any time during the maintenance phase: clinical worsening (defined as Clinical Global Impression-Improvement [CGI-I] score [?] 5 plus increase in any core PANSS item), hospitalization, risk of suicide, or violent behavior. The aripiprazole group had a significantly delayed time to relapse ($P < 0.0001$) and showed a significantly lower rate of relapse compared with the placebo group (9.6% vs. 36.8%, respectively) (Kane *et al.* 2012). The second investigation was a 38-week double-blind noninferiority study that compared relapse rates for aripiprazole once-monthly 400-mg depot injection, oral aripiprazole (10-30 mg/day), and aripiprazole once-monthly 50-mg depot injection, with criteria similar to those used in the Kane *et al.* (2012) study (discussed above). There were no significant differences in rates of relapse between the once-monthly 400-mg depot formulation (7.12%) and the 10-30 mg/day oral formulation (7.76%), and both were significantly superior to the 50-mg depot formulation (21.8%; $P < 0.0001$) (Fleischhacker *et al.* 2014).

One 12-week randomized, double-blind, placebo-controlled Phase III multicenter trial evaluated the efficacy of the aripiprazole once-monthly injection for the management of acute exacerbations in chronic schizophrenia. Patients were randomly assigned to either the aripiprazole once-monthly 400-mg injection group with concomitant oral aripiprazole (mean daily dosage 12.8 mg) for 2 weeks ($n = 168$) or the placebo group ($n = 172$). The aripiprazole group showed sustained improvements in PANSS-Total scores, PANSS-Positive and -Negative subscale scores, and CGI-I scores, with improvements apparent within the first week of administration (Kane *et al.* 2014).

An open-label mirror-image multicenter study in a naturalistic community setting (Kane *et al.* 2013) compared total psychiatric hospitalization rates in 183 patients (18-65 years) who had previously been treated with oral antipsychotics (retrospective phase) and who were then switched to the aripiprazole once-monthly depot formulation for 6 months (prospective phase). The rate of hospitalization for the 6-month prospective phase (14.2%) was found to be lower than the rate for the 6-month retrospective oral antipsychotic period (41.5%; $P < 0.0001$).

Meltzer *et al.* (2015) conducted a 12-week double-blind, placebo-controlled multicenter study comparing once-monthly administration of aripiprazole lauroxil 441 mg or 882 mg versus placebo for 12 weeks. Statistically significant improvement was observed on the PANSS-Total score from baseline to day 85 in both medication groups, with placebo-adjusted differences of [?] 10.9 ($P < 0.001$) and [?] 11.9 ($P < 0.001$) for aripiprazole lauroxil 441 mg and 882 mg, respectively.

The efficacy of the aripiprazole lauroxil 2-month injection with 1-day initiation was evaluated against paliperidone palmitate injection in a 25-

week double-blind study of adult patients with acute exacerbations of schizophrenia in an inpatient setting (Weiden *et al.* 2020). Patients were randomly assigned to receive paliperidone palmitate (234 mg on day 1, 156 mg on day 8, and then 156 mg q 4 weeks) or aripiprazole (aripiprazole lauroxil NanoCrystal Dispersion + oral aripiprazole 30 mg on day 1, aripiprazole lauroxil 1,064 mg on day 8, and then 1,064 mg q 8 weeks) for 25 weeks. For the aripiprazole lauroxil group, the PANSS-Total score was significantly reduced from baseline at weeks 4 ([?] 17.4; $P < 0.001$), 9 ([?] 19.8), and 25 ([?] 23.3). Paliperidone palmitate also had similar reductions in the PANSS-Total score.

Bipolar Disorder

The efficacy of aripiprazole in the treatment of acute manic episodes was established in two 3-week placebo-controlled trials of hospitalized patients whose symptoms met DSM-IV (American Psychiatric Association 1994) criteria for bipolar I disorder with manic or mixed episodes (Keck *et al.* 2003; Sachs *et al.* 2006). Aripiprazole was superior to placebo in reducing the Young Mania Rating Scale (YMRS) total score and the Clinical Global Impression-Bipolar (CGI-BP) Severity of Illness score. In a third large randomized, double-blind trial (Vieta *et al.* 2005), aripiprazole was compared with haloperidol in the treatment of acute bipolar mania over a 12-week period. Significantly more patients remained in treatment and were classified as responders (50% reduction in YMRS score from baseline) at week 12 in the aripiprazole group (49.7%) than in the haloperidol group (28.4%). EPS adverse events were more frequent with haloperidol than with aripiprazole (62.7% vs. 24.0%).

The efficacy of adjunctive aripiprazole with concomitant lithium or valproate in the treatment of manic or mixed episodes was established in a 6-week placebo-controlled study with a 2-week lead-in mood stabilizer monotherapy phase in adult patients who met DSM-IV criteria for bipolar I disorder (Vieta *et al.* 2008). Adjunctive aripiprazole starting at 15 mg/day with concomitant lithium or valproate (in a therapeutic range of 0.6-1.0 mEq/L or 50-125 g/mL, respectively) was found to be superior to lithium or valproate with adjunctive placebo on the basis of reductions in YMRS total scores and CGI-BP Severity of Illness scores.

Aripiprazole monotherapy was evaluated in the treatment of nonpsychotic depressive episodes associated with bipolar I disorder. The results of two identically designed 8-week randomized, double-blind, placebo-controlled multicenter studies were reported by Thase *et al.* (2008). The primary outcome measure was mean change from baseline to week 8 on the Montgomery-Asberg Depression Rating Scale (MADRS) total score. Although statistically significant differences were observed during weeks 1-6, there were no significant differences in change in MADRS total score between aripiprazole and placebo at week 8 in either study.

To evaluate the long-term effectiveness of aripiprazole in delaying relapse in bipolar I disorder, a trial was conducted of patients whose symptoms met DSM-IV criteria for bipolar I disorder with a recent manic or mixed episode (Keck *et al.* 2006). Patients whose condition had been stabilized while taking open-label aripiprazole and who had maintained a clinical response for at least 6 weeks were randomly assigned to receive either aripiprazole or placebo for the 26-week double-blind phase. Aripiprazole-treated patients had significantly fewer relapses than did placebo-treated patients (25% vs. 43%). Aripiprazole was superior to placebo in delaying the time to manic relapse but did not differ from placebo in delaying time to depressive relapse.

The efficacy of the aripiprazole long-acting depot injection in the maintenance treatment of bipolar I disorder was evaluated in a 52-week double-blind, placebo-controlled withdrawal phase study of patients stabilized on oral aripiprazole and transitioned to either 400 mg of the long-acting depot injection or placebo injection (Calabrese *et al.* 2018). The aripiprazole once-monthly injection significantly increased time to hospitalization for any mood episode compared with placebo ($P = 0.0002$), with recurrence rates of 2.3% and 13.5%, respectively.

The efficacy of aripiprazole in the treatment of bipolar I disorder in pediatric patients (ages 10-17 years) was evaluated in two studies. The first study was a 4-week double-blind, placebo-controlled trial of outpatients whose symptoms met DSM-IV criteria for bipolar I disorder manic or mixed episodes with or without psychotic features. The trial compared two fixed daily dosages of aripiprazole (10 mg or 30 mg). Both dosages of aripiprazole were superior to placebo as measured by change from baseline to week 4 on the YMRS total score (Otsuka Pharmaceutical 2020a). The second study was a 30-week randomized, placebo-controlled study of 210 patients (ages 10-17 years) with bipolar I disorder (manic or mixed) with or without psychotic features who were randomly assigned to receive oral aripiprazole 10 mg/day, oral aripiprazole 30 mg/day, or placebo. Both dosages of aripiprazole were superior to placebo; at week 30, aripiprazole-treated patients demonstrated significantly greater improvement in YMRS total scores compared with placebo-treated patients (Findling *et al.* 2013).

Adjunctive Treatment of Major Depressive Disorder

The efficacy of aripiprazole in the adjunctive treatment of MDD was demonstrated in four short-term (6-week) placebo-controlled trials (Berman *et al.* 2007, 2009; Kamijima *et al.* 2018; Marcus *et al.* 2008). During the prospective antidepressant treatment period, patients received one of several antidepressants (escitalopram, fluoxetine, paroxetine controlled release, sertraline, or venlafaxine extended release), each with a single-blind adjunctive placebo. Patients with incomplete response continued taking the antidepressant and were randomly assigned to receive double-blind adjunctive placebo or adjunctive aripiprazole (2-15 mg/day with the potent CYP2D6 inhibitor fluoxetine or paroxetine; 2-20 mg/day with all other antidepressants). In all three trials, the mean change in MADRS total score was significantly greater with adjunctive aripiprazole than with adjunctive placebo. Akathisia and restlessness were significantly more common with adjunctive aripiprazole than with adjunctive placebo.

Fava *et al.* (2012) evaluated the efficacy of low-dosage aripiprazole added to antidepressant therapy for individuals with MDD who had experienced an inadequate response to prior antidepressant treatment. A total of 225 patients were randomly assigned

to receive adjunctive treatment with aripiprazole 2 mg/day or placebo. The pooled, weighted response difference between aripiprazole 2 mg/day and placebo was 5.6% (*P* = 0.18; not significant); the difference on the MADRS was 1.51 (*P* = 0.065; not significant). Of note, there was no difference in rates of akathisia with low-dosage aripiprazole compared with placebo. Thus, a reasonable initial therapeutic approach may be to try a low-dosage (2 mg/day) augmentation of aripiprazole, in view of its better tolerability, and to increase the dosage to 5 mg/day, and if necessary to 10 or 15 mg/day, in the face of continued nonresponse, given that the efficacy of the higher dosage range was supported by robust evidence in three previous positive studies (Fava *et al.* 2012).

In a 36-week multisite study of 1,522 patients with MDD treated at 35 U.S. Veterans Health Administration medical centers, the efficacy of aripiprazole augmentation was evaluated in the treatment of patients unresponsive to at least one antidepressant (Mohamed *et al.* 2017). Patients were randomly assigned to receive adjunctive aripiprazole (2-15 mg), switch to bupropion, or augment with bupropion, with a primary outcome of remission as measured by the 16-item Quick Inventory of Depressive Symptomatology-Clinician Rated score. After the acute treatment phase of 12 weeks, remission rates were 22.3% for the switch group, 26.9% for the bupropion augmentation group, and 28.9% for the aripiprazole augmentation group. The aripiprazole augmentation group was significantly more likely to remit than the switch group (*P* = 0.02).

Irritability in Autism Spectrum Disorder

The efficacy of aripiprazole in the treatment of irritability associated with DSM-IV autistic disorder was established in two 8-week placebo-controlled trials of children and adolescents (ages 6-17 years). Efficacy was evaluated with two assessment scales: the Aberrant Behavior Checklist (ABC) and the CGI-I scale. In the first trial (Owen *et al.* 2009), pediatric patients with DSM-IV autistic disorder received aripiprazole (2-15 mg/day, based on clinical response) or placebo. Patients who received aripiprazole (at a mean daily dosage of 8.6 mg at the end of the 8-week treatment) demonstrated significantly improved scores on the ABC-Irritability (ABCI) subscale and on the CGI-I scale compared with patients who received placebo. In the other trial (Marcus *et al.* 2009), three fixed dosages of aripiprazole (5, 10, or 15 mg/day) were compared with placebo. All three dosages of aripiprazole were associated with significantly greater improvement in scores on the ABC-I subscale compared with placebo.

The efficacy and safety of aripiprazole in the long-term maintenance treatment of pediatric patients with irritability associated with DSM-IV autistic disorder were evaluated in a double-blind, randomized, placebo-controlled multicenter study of patients ages 6-17 years. After an initial phase in which single-blind aripiprazole was flexibly dosed (2-15 mg/day; average dosage of 9.0 mg/day) for 13-26 weeks to establish a stable response (defined as a 25% decrease on the ABC-I subscale and a rating of "much improved" or "very much improved" on the CGI-I scale), patients were randomly assigned to receive either aripiprazole (*n* = 41; 2-15 mg/day) or placebo (*n* = 44) for 16 weeks or until relapse. The primary outcome measure was time from randomization to relapse. No statistically significant differences in time to relapse were seen between the drug and the placebo group (*P* = 0.97; hazard ratio, 0.57; number needed to treat, 6) (Findling *et al.* 2014).

Tourette's Disorder

The efficacy of aripiprazole for children and adolescents with Tourette's disorder was established in two short-term trials. In the first study, a double-blind, randomized, placebo-controlled, flexible-dose multicenter trial, patients with Tourette's disorder (*n* = 61) ages 6-18 years were randomly assigned to receive either placebo or aripiprazole (2-20 mg/day) for 10 weeks. Aripiprazole-treated patients demonstrated significantly greater reductions in Yale Global Tic Severity Scale scores compared with patients receiving placebo ([?] 15.0 [8.4] and [?] 9.6 [8.8], respectively; *P* = 0.0196) (Yoo *et al.* 2013). The mean change in phonic tic scores favored the aripiprazole group, but there was no difference in motor tic scores. Treatment-emergent adverse events were not statistically significantly different. The mean dosage was 11.0 mg/day (Yoo *et al.* 2013). In the second study, a Phase III randomized, double-blind, placebo-controlled multicenter trial in patients with a diagnosis of Tourette's disorder (ages 7-17 years), patients first underwent a 3-to 42-day washout period (Sallee *et* *al.* 2017). A total of 133 patients were then randomly assigned to receive low-dosage aripiprazole (5 mg/day if < 50 kg, 10 mg/day if [?] 50 kg), high-dosage aripiprazole (10 mg/day if < 50 kg, 20 mg/day if [?] 50 kg), or placebo for 8 weeks. Both the low-dosage and high-dosage aripiprazole groups showed significant improvement in Yale Global Tic Severity Scale and CGI-Tourette's Syndrome Scale scores compared with the placebo group (Sallee *et al.* 2017).

Off-Label Use

De Deyn *et al.* (2005) compared the efficacy, safety, and tolerability of aripiprazole versus placebo in patients with psychosis associated with Alzheimer's disease in a 10-week double-blind multicenter study. The initial aripiprazole dosage of 2 mg/day was titrated upward (to 5, 10, or 15 mg/day) according to efficacy and tolerability; evaluations included the Neuropsychiatric Inventory (NPI) Psychosis subscale and the BPRS. Aripiprazole-treated patients showed significantly greater improvements from baseline in BPRS-Psychosis subscale and BPRS-Core subscale scores at endpoint compared with patients receiving placebo.

In another double-blind multicenter study (Mintzer *et al.* 2007), patients with psychosis associated with Alzheimer's disease were randomly assigned to receive either placebo or aripiprazole 2, 5, or 10 mg/day. The primary efficacy measure was mean change from baseline to week 10 on the Neuropsychiatric Inventory-Nursing Home (NPI-NH) Psychosis subscale score. Aripiprazole 10 mg/day showed significantly greater improvements than placebo on all efficacy measures (NPI-NH Psychosis subscale, CGI-Severity, BPRS Total and Core, and Cohen-Mansfield Agitation Inventory scores). Aripiprazole 5 mg/day showed significant improvements compared with placebo on BPRS and Cohen-Mansfield Agitation Inventory scores. Aripiprazole 2 mg/day was not efficacious. No antipsychotic is currently approved in the United States for treating the behavioral and psychotic symptoms that often accompany dementia, and all antipsychotics carry a bolded warning based on increased mortality observed in older patients with dementia-related psychosis treated with these agents.

In a 12-week double-blind study (Findling *et al.* 2017), pediatric patients (ages 5-17) with high genetic risk for bipolar disorder and subclinical symptoms of elevated or irritable mood (cyclotaxia) were randomly assigned to receive oral aripiprazole or placebo. Aripiprazole was superior to placebo in reduction from baseline of YMRS total scores ($P < 0.005$).

Nickel *et al.* (2006) conducted a double-blind, placebo-controlled study in patients whose clinical presentation met DSM-III-R (American Psychiatric Association 1987) criteria for borderline personality disorder. Subjects were randomly assigned in a 1:1 ratio to receive either aripiprazole (15 mg/day) or placebo for 8 weeks. At endpoint, significant changes in scores on most scales of the Symptom Checklist-90 Revised, on the Hamilton Rating Scale for Depression (Ham-D), on the Hamilton Anxiety Scale (Ham-A), and on all subscales of the State-Trait Anger Expression Inventory were observed in subjects who received aripiprazole. The improvements observed at 8 weeks were maintained at 18-month follow-up (Nickel *et al.* 2007).

Tiihonen *et al.* (2007) conducted a study in which patients whose symptoms met DSM-IV criteria for intravenous amphetamine dependence were randomly assigned to receive aripiprazole (15 mg/day), slow-release methylphenidate (54 mg/day), or placebo for 20 weeks. The study was terminated prematurely because of unexpected results in the interim analysis. Contrary to the hypothesized result, patients who received aripiprazole treatment had significantly more amphetamine-positive urine samples than did patients in the placebo group, and patients who received methylphenidate had significantly fewer amphetamine-positive urine samples than patients who received placebo.

The efficacy of aripiprazole in the treatment of schizophrenia comorbid with active cocaine dependence was evaluated in an 8-week double-blind study (Beresford *et al.* 2017). Patients ($N = 44$) were randomly assigned to receive either aripiprazole (15-30 mg/day) or perphenazine (4-8 mg doses given three times/day), with a primary outcome of cocaine-free urine samples and a secondary outcome of reductions in craving scores. Cocaine-free urine samples did not differ between groups. Cravings, in respect to intensity, frequency, and duration, were seen to decrease in the aripiprazole group by week 6 but did not correlate with reduced cocaine use by study endpoint.

In a 12-week double-blind, placebo-controlled multicenter trial (Anton *et al.* 2008) evaluating the efficacy of aripiprazole for patients with DSM-IV alcohol dependence, aripiprazole did not differ from placebo on the study's primary efficacy measure, mean percentage of days abstinent.

The efficacy of aripiprazole (up to 15 mg/day) and topiramate in reducing alcohol-related outcomes was evaluated in a 5-week double-blind, placebo controlled, between-subject human laboratory study (Haass-Koffler *et al.* 2018). Aripiprazole did not result in significant changes in alcohol use or cravings.

Brexpiprazole

Brexpiprazole is currently approved in the United States for schizophrenia in both adults and pediatric patients ages 13-17 years and for use as an adjunct to antidepressant treatment for adults with MDD who have had an inadequate response to antidepressant therapy (Otsuka Pharmaceutical 2023). In 2023, brexpiprazole became the first pharmacological agent to receive FDA approval for treatment of agitation associated with dementia due to Alzheimer's disease (Otsuka Pharmaceutical 2023).

Schizophrenia

The efficacy of brexpiprazole in the treatment of acute symptom exacerbations in schizophrenia has been evaluated in multiple studies, including two 6-week double-blind, placebo-controlled multicenter trials. In the BEACON Phase III multicenter

study, patients with acute schizophrenia were randomly assigned to receive aripiprazole (1, 2, or 4 mg/day) or placebo. Brexpiprazole 4 mg/day produced statistically significant reductions ([?] 6.47; *P* = 0.0022) compared with placebo in the PANSS-Total score (Kane *et al.* 2015). In another 6-week multicenter double-blind, placebo-controlled Phase III trial (VECTOR study), patients with schizophrenia experiencing an acute exacerbation were randomly assigned to receive brexpiprazole (0.25, 2, or 4 mg/day) or placebo. At 6 weeks, both the 2 mg/day and the 4 mg/day dosages of brexpiprazole had produced statistically significantly greater reductions ([?] 8.72 [$P < 0.0001$] and [?] 7.64 [$P = 0.0006$] for 2 mg/day and 4 mg/day, respectively) in PANSS-Total scores compared with placebo (Correll *et al.* 2015).

A Phase III 52-week maintenance study was conducted to demonstrate the effectiveness of brexpiprazole in preventing exacerbation or relapse of psychosis in patients with schizophrenia. Patients with acute exacerbation of psychotic symptoms were started on brexpiprazole (flexible dosing) over 1-4 weeks. Those who met the stability criteria for 12 weeks were randomly assigned to double-blind maintenance treatment with brexpiprazole or placebo for up to 52 weeks. The time to impending relapse was significantly delayed with brexpiprazole treatment compared with placebo (Fleischhacker *et al.* 2017). A similar result for tolerability and efficacy was replicated in another Phase III randomized, double-blind, placebo-controlled study over the course of 52 weeks (Forbes *et al.* 2018).

There are limited head-to-head studies comparing brexpiprazole with other antipsychotics. An exploratory, open-label study was conducted to evaluate the effects of brexpiprazole and aripiprazole. Patients with acute exacerbation of schizophrenia were randomly assigned to brexpiprazole (3 mg/day target dose) and aripiprazole (15 mg/day target dose). Results showed a clinically relevant improvement in psychopathology and a reduction in the PANSS-Total scores in both brexpiprazole and aripiprazole treatment groups ([?] 22.9 and [?] 19.4, respectively; $P < 0.0001$) (Citrome *et al.* 2016). Additionally, the study found that brexpiprazole had a lower incidence of akathisia (9.4%) compared with that of aripiprazole (21.2%) (Citrome *et al.* 2016). The comparable response rate of aripiprazole and brexpiprazole was also supported by findings in recent meta-analyses (Huhn *et al.* 2019; Kishi *et al.* 2020). In the meta-analysis comparing brexpiprazole and aripiprazole, the ranked probability results showed that brexpiprazole had a lower incidence of side effects and a better risk-benefit ratio than aripiprazole in the treatment of patients with acute schizophrenia (Kishi *et al.* 2020). Brexpiprazole was also compared with quetiapine in a large, double-blind, placebo-controlled trial (LIGHTHOUSE study), where both were found to produce a clinically relevant reduction in PANSS-Total score; however, brexpiprazole failed to reach statistical significance compared with placebo, possibly because of an unexpectedly high placebo response (Frampton 2019).

Adjunctive Treatment of Major Depressive Disorder

The antidepressant effect of brexpiprazole may be attributable to its 5-HT$_{1A}$ and D$_2$ partial agonism and 5-HT$_7$ and a$_2$ antagonism, but the exact mechanism remains unknown. The efficacy of brexpiprazole in the adjunctive treatment of MDD has been demonstrated in two pivotal randomized, double-blind Phase III studies. In the first study (Thase *et al.* 2015a), patients who had not responded to three prior trials with antidepressants entered an 8-week prospective period of open-label treatment with an antidepressant. Patients who showed inadequate response (defined as a score of [?] 14 on the 17-item Ham-D, < 50% reduction from baseline in Ham-D and MADRS total scores, and a CGI-I score of [?] 3) were randomly assigned to receive double-blind antidepressant plus brexpiprazole (2 mg/day) or antidepressant plus placebo. Adjunctive brexpiprazole 2 mg/day produced statistically significant reductions in MADRS total scores compared with adjunctive placebo ([?] 8.36 vs. [?] 5.15, respectively; $P = 0.0002$) (Thase *et al.* 2015a).

The second study (Thase *et al.* 2015b) also evaluated the efficacy and safety of brexpiprazole (1 mg and 3 mg/day) versus placebo in the adjunctive treatment of antidepressant-resistant MDD. The study also included an 8-week single-blind prospective treatment phase in which patients received one antidepressant. Patients who had an inadequate response (defined as a Ham-D score [?] 14, < 50% reduction from baseline in Ham-D and MADRS total scores, and a CGI score [?] 3) were randomly assigned to receive double-blind antidepressant plus brexpiprazole (1 mg/day or 3 mg/day) or antidepressant plus placebo. The brexpiprazole 3 mg/day treatment group showed statistically significantly greater improvement (assessed by mean reduction from baseline in MADRS total score) compared with the placebo group ([?] 8.29 vs. [?] 6.33, respectively; $P = 0.0079$), whereas the numerical improvement in MADRS total score was not statistically significantly greater for brexpiprazole 1 mg/day versus placebo ([?] 7.64; $P = 0.0079$) (Thase *et al.* 2015b).

Additional studies and reviews have examined the efficacy of brexpiprazole as an augmentation agent for MDD, yielding some mixed results. Yoon *et al.* (2017) conducted a meta-analytic study to evaluate the use of brexpiprazole in randomized controlled trials involving patients with MDD. Findings showed that brexpiprazole had greater mean differences in the score changes for the MADRS ([?] 1.76; $P < 0.00001$) and the Ham-D ([?] 1.21; $P < 0.00001$) compared with placebo, especially at higher dosages (1-3 mg/day). In the same study, the meta-analysis of negative studies also yielded positive results in MADRS score reductions ([?] 1.19; $P = 0.03$) and Ham-D score reductions ([?] 0.76; $P = 0.03$) compared with placebo. Additionally, the study showed a higher frequency of responders ([?] 50% reduction in MADRS score) and remitters (MADRS score [?] 10 with [?] 50% reduction) with brexpiprazole use, with risk ratios of 1.57 ($P < 0.00001$) and 1.55 ($P = 0.0004$), respectively (Yoon *et al.* 2017). Head-to-head studies comparing the efficacy of adjunctive brexpiprazole against that of other adjunctive atypical antipsychotics remain limited, but the overall efficacy appears to be comparable at this time.

Agitation Associated With Dementia due to Alzheimer's Disease

Two Phase III randomized, double-blind, placebo-controlled, fixed-dose studies were conducted to establish the efficacy of brexpiprazole in the treatment of agitation associated with dementia due to Alzheimer's disease (Otsuka Pharmaceutical 2023). Both studies required participants to have a diagnosis of probable Alzheimer's disease, a Mini-Mental State Examination (MMSE) score of [?] 5 and [?] 22, and sufficient agitated behavior(s) to warrant use of pharmacotherapy. The Cohen-Mansfield Agitation Inventory (CMAI) total score was used to measure the frequency of agitated behavior, with the primary endpoint focused on change between baseline and week 12 of participation. Participant ages ranged from 51 to 90 years.

In the first Phase III study, participants were randomly assigned to one of three groups: placebo, oral dosage of 1 mg/day, and oral dosage of 2 mg/day. Both medication groups were started at a dosage of 0.25 mg once daily, which was titrated over the course of the study to the respective assigned dosage goals. At the completion of the 12-week trial, the 2 mg/day group demonstrated statistically significantly greater improvement in the CMAI total score in comparison with the placebo group, with an adjusted mean difference of -3.8 (*P* = 0.04) (Grossberg *et al.* 2020).

In the second Phase III study, participants were randomly assigned to one of three groups: placebo, oral dosage of 2 mg/day, and oral dosage of 3 mg/day. Both medication groups were started at 0.5 mg once daily, with the dosage increased over the course of the study period to the respective assigned dosage goals. At the completion of the 12-week trial, the 2 mg/day and 3 mg/day groups showed improved total CMAI scores in comparison with the placebo group, with an adjusted mean difference of -5.3 (Otsuka Pharmaceutical 2023).

Two Phase III clinical trials showed the efficacy of brexpiprazole 2 mg/day (flexible and fixed dosing) for the treatment of agitation in patients with Alzheimer's disease. The studies also demonstrated an improved tolerability and safety profile for brexpiprazole in comparison with the currently available second-generation antipsychotics (Caraci *et al.* 2020; Grossberg *et al.* 2020). It is important to note that these two trials excluded patients with a history of stroke or vascular dementia. Also of note, antipsychotics are not FDA approved for the treatment of behavioral problems associated with dementia because of the black box warning of an increased risk of mortality in this population (Otsuka Pharmaceutical 2023).

These Phase III studies demonstrated brexpiprazole's improved tolerability and safety (supported by use of a slow titration schedule) in comparison with the other available second-generation antipsychotics in the treatment of agitation in patients with Alzheimer's disease (Caraci *et al.* 2020). However, brexpiprazole is not indicated as a prn (as needed) treatment for agitation in patients with Alzheimer's disease (Otsuka

Pharmaceutical 2023). Additionally, antipsychotics are not FDA approved for the treatment of behavioral problems associated with dementia because of the black box warning for an increased risk of mortality in this population (Otsuka Pharmaceutical 2023).

Off-Label Use

Brexpiprazole has a higher affinity for serotonin 5-HT_{1A}, 5-HT_{2A}, and 5-HT_7 receptors, which may help it exert an anxiolytic effect in addition to antidepressant effects (Yoon *et al.* 2017). In the post hoc analyses of three placebo-controlled studies in adults with MDD and inadequate response to antidepressants, adjunctive brexpiprazole dosages (2 mg and 3 mg/day) have been shown to significantly reduce the total Ham-A score (Thase *et al.* 2018). Of note, the benefits were seen in the subgroups of depressed patients with anxious distress, who may be less likely to respond to antidepressant monotherapy. Therefore, brexpiprazole may offer another potential option for individuals struggling with depressive symptoms for which anxiety is part of the presentation.

Side Effects and Toxicology

Aripiprazole

A pooled analysis of safety and tolerability data from the five short-term studies (Marder *et al.* 2003; Stock *et al.* 2002) showed that aripiprazole treatment was well tolerated.

The most commonly reported adverse events with aripiprazole were headache, insomnia, agitation, and anxiety, which were similar in the aripiprazole and placebo groups. The adverse-event profile of aripiprazole did not vary according to patient characteristics of age, sex, and race or ethnicity, and no deaths were reported during the short-term studies. Data from four fixed-dosage studies (Bristol Myers Squibb 2001; Cutler *et al.* 2006; Kane *et al.* 2002; Potkin *et al.* 2003) showed that somnolence was the only adverse event seen with aripiprazole that was possibly dose related. Objective rating scale assessments were used to measure changes in parkinsonian symptoms (Simpson-Angus Scale [SAS]), dyskinesias (Abnormal Involuntary Movement Scale), and akathisia (Barnes Akathisia Rating Scale [BARS]). SAS scores with aripiprazole did not differ significantly from those with placebo, whereas Abnormal Involuntary Movement Scale scores improved significantly from baseline with aripiprazole compared with placebo. Aripiprazole did not produce consistent dose-dependent changes in BARS scores.

According to the FDA-approved package insert, treatment-emergent adverse events most commonly reported with aripiprazole (occurring in 10% of patients with an incidence greater than that with placebo) in short-term trials of patients with schizophrenia (up to 6 weeks) or bipolar disorder (up to 3 weeks), respectively, included headache (aripiprazole 30% vs. placebo 25%), anxiety (20% vs. 17%), insomnia (19% vs. 14%), nausea (16% vs. 12%), vomiting (12% vs. 6%), dizziness (11% vs. 8%), constipation (11% vs. 7%), dyspepsia (10% vs. 8%), and akathisia (10% vs. 4%) (Otsuka Pharmaceutical 2020a).

The most common adverse events reported for the aripiprazole long-acting injectable formulation in the Kane *et al.* (2012) 52-week trial were insomnia (aripiprazole 10% vs. placebo 9%), tremor (5.9% vs. 1.5%), headache (5.9% vs. 5.2%), and akathisia (5.6% vs. 6%). In the Kane *et al.* (2014) 12-week acute management of schizophrenia study, the most common adverse events were weight gain (aripiprazole 16.8% vs. placebo 7%), headache (14.4% vs. 16.3%), and akathisia (11.4% vs. 3.5%). There was no significant difference in rates of EPS other than akathisia between the 400-mg aripiprazole group and the placebo group. In a 24-week open-label parallel-arm study conducted by Mallikaarjun *et al.* (2013), the tolerability and safety of aripiprazole once monthly in schizophrenia were comparatively evaluated for dosages of 200 mg, 300 mg, and 400 mg. The most common adverse events were injection-site pain (aripiprazole 400 mg, 28.6%), tremor (aripiprazole 300 mg, 6.7%; aripiprazole 400 mg, 21.4%), and vomiting (aripiprazole 300 mg, 13.3%; aripiprazole 400 mg, 14.3%).

The most common adverse events in a 12-week Phase III trial of aripiprazole lauroxil in the treatment of acute exacerbations of schizophrenia were akathisia, headache, insomnia, and injection-site pain (occurring in 5% of patients). Akathisia occurred at twice the rate of placebo for aripiprazole lauroxil 882 mg and 441 mg (4.3%, 11.6%, and 11.5%, respectively) (Meltzer *et al.* 2015). The majority (> 75%) of akathisia episodes occurred within 3 weeks of receiving the first injection. In a 52-week safety study (Nasrallah *et al.* 2019) of patients with schizophrenia taking aripiprazole lauroxil, weight gain was minimal (0.8 kg), with no statistically significant changes in metabolic parameters at the end of the study period.

Minimal changes in mean body weight were observed with aripiprazole treatment in short-term studies (pooled data, 0.71 kg) (Marder *et al.* 2003) and in long-term studies (26-week, [?] 1.26 kg; 52-week, + 1.05 kg) (Kasper *et al.* 2003; Pigott *et al.* 2003).

Olanzapine and aripiprazole were compared on their propensity to cause weight gain and other metabolic disturbances in a 26-week randomized, double-blind multicenter trial (McQuade *et al.* 2004). Statistically significant differences in mean weight change between treatments were observed beginning at week 1 and were sustained throughout the study. At week 26, there was a mean weight loss of 1.37 kg (3.04 lb) with aripiprazole compared with a mean weight gain of 4.23 kg (9.40 lb) with olanzapine among patients who continued therapy ($P < 0.001$). Changes in fasting plasma levels of total cholesterol, high-density lipoprotein cholesterol, and triglycerides were significantly different in the two treatment groups, with worsening of the lipid profile among patients treated with olanzapine.

Aripiprazole treatment was not associated with increases in prolactin levels during either short-or long-term studies. In fact, prolactin levels have been shown to be slightly decreased by aripiprazole (Crespo-Facorro *et al.* 2017).

Overall, aripiprazole treatment is associated with a low incidence of EPS (other than akathisia) and EPS-related symptoms and with minimal or no effects on weight gain, QTc interval, or circulating levels of cholesterol, glucose, and prolactin. Treatment with aripiprazole may reduce the burden of antipsychotic-associated side effects, leading to improved patient adherence and decreased risks of acute relapse.

Brexpiprazole

Overall, brexpiprazole has been well tolerated in the four short-term clinical trials conducted thus far, with lower rates of discontinuation due to adverse events compared with placebo (Citrome 2015). In pooled analyses of brexpiprazole in the adjunctive treatment of MDD, the rate of discontinuation due to adverse reactions for all dosages of brexpiprazole was 3%, compared with 1% for placebo (Otsuka Pharmaceutical 2023). In the two Phase III trials of brexpiprazole in acute schizophrenia, the overall rates of discontinuation due to adverse events for brexpiprazole were lower than those for placebo (Correll *et al.* 2015; Kane *et al.* 2015).

The most common side effects varied among available studies. In one Phase III trial in acute schizophrenia, the most common adverse events for brexpiprazole were headache, agitation, and insomnia, with rates of akathisia lower than those with placebo but with a dose-dependent increase for brexpiprazole (Kane *et al.* 2015). Comparatively, the most common adverse event in another Phase III trial was akathisia for brexpiprazole 2 mg (4.4%) and 4 mg (7.2%) versus placebo (2.2%), with akathisia most commonly occurring within the first 3 weeks of treatment (Correll *et al.* 2015). Akathisia is more likely at dosages above 4 mg/day (Kane *et al.* 2016), but the incidence of akathisia for brexpiprazole (9.5%) is still lower than that for aripiprazole (21.2%) (Citrome *et al.* 2016), probably because of brexpiprazole's stronger 5-HT_{2A} antagonism (Correll *et al.* 2016).

Brexpiprazole has a lower incidence of sedation and somnolence due to its low affinity for receptors associated with sedation (e.g., H_1) (Correll *et al.* 2016). It has also not been found to have a significant impact on QTc (McEvoy and Citrome 2016). Pooled data from two short-term Phase III schizophrenia trials showed that 10% of brexpiprazole-treated patients had weight gains of [?] 7% from baseline during a 6-week trial, compared with 4.1% of patients receiving placebo (Citrome 2015; Otsuka Pharmaceutical 2023). Similarly, the pooled data from both short-term MDD trials showed weight gain in the brexpiprazole group to be higher than that in the placebo group (6.7% vs. 1.9%), with the greatest increase being 1.6 kg for brexpiprazole 3 mg/day at 6 weeks (Citrome 2015; Otsuka Pharmaceutical 2023). Although most antipsychotics have been associated with chronic elevated risk of metabolic changes, brexpiprazole is less likely to affect triglyceride concentrations and may be associated with better metabolic outcomes (Pillinger *et al.* 2020), although moderate weight gain may be seen in short-and long-term treatment (Newcomer *et al.* 2019).

Change in prolactin level was studied in all treatment trials. In one Phase III trial of brexpiprazole in schizophrenia, there was no statistically significant change in prolactin level (Correll *et al.* 2015). In a second Phase III short-term trial of brexpiprazole in schizophrenia, the incidence of potentially clinically relevant prolactin values (one to two times the upper limit of normal) was highest in the brexpiprazole 4 mg/day group (19.1%) compared with the placebo group (13.9%) (Kane *et al.* 2015). In a short-term Phase III trial of brexpiprazole in the adjunctive treatment of MDD, 0.4% of patients receiving brexpiprazole 3 mg/day, compared with 1.4% of patients receiving placebo, had a prolactin level greater than three times the upper limit of normal (Thase *et al.* 2015a).

The incidence of EPS was evaluated in all four short-term treatment trials by means of the BARS and the SAS (Otsuka Pharmaceutical 2023). The percentage of patients treated with brexpiprazole plus an antidepressant who showed a shift from normal to abnormal was greater compared with placebo for both the BARS (4% vs. 0.6%) and the SAS (4% vs. 3%) (Otsuka Pharmaceutical 2023). Similarly, the brexpiprazole group showed a greater shift from normal to abnormal compared with placebo in both the BARS (2% vs. 1%) and the SAS (7% vs. 5%) in pooled data from both schizophrenia trials (Otsuka Pharmaceutical 2023). Additionally, brexpiprazole was found to have a lower risk of D_2 receptor sensitization after a subacute treatment in an animal study, further suggesting its lower risk of EPS in the long term (Amada *et al.* 2019).

With an overall minimal incidence of EPS beyond akathisia and minimal observed changes in QTc, lipid panel, and glucose panel values compared with placebo, brexpiprazole is another antipsychotic with a tolerable side-effect profile that may improve adherence in the long term (Correll *et al.* 2015; Kane *et al.* 2015; Thase *et al.* 2015a, 2015b).

Drug-Drug Interactions

Aripiprazole

Because aripiprazole is metabolized primarily by the hepatic enzymes CYP2D6 and CYP3A4, it has the potential to interact with other substrates for these enzymes. Inducers of these enzymes may increase clearance and thereby reduce blood levels of aripiprazole, whereas inhibitors of CYP3A4 or CYP2D6 may inhibit elimination and thereby increase blood levels of aripiprazole. In vivo studies showed decreased levels of aripiprazole and dehydroaripiprazole in the plasma when aripiprazole was coadministered with carbamazepine, a CYP3A4 inducer. The aripiprazole dosage should therefore be increased when the drug is administered concomitantly with carbamazepine. Findings from in vivo studies that coadministered aripiprazole with ketoconazole (a CYP3A4 inhibitor) or with quinidine (a CYP2D6 inhibitor) suggest that the aripiprazole dosage should be reduced when aripiprazole is administered with strong CYP3A4 or CYP2D6 inhibitors. Aripiprazole exhibits a_1-adrenergic receptor antagonist activity and therefore may enhance the effects of certain antihypertensive agents (Otsuka Pharmaceutical 2020a).

Brexpiprazole

Brexpiprazole is metabolized primarily by hepatic CYP enzymes 2D6 and 3A4; therefore, coadministration with inducers or inhibitors of these CYP enzymes requires dosage adjustments for brexpiprazole. In vivo studies showed increased levels of brexpiprazole when it was coadministered with ketoconazole (a CYP3A4 inhibitor) or quinidine (a CYP2D6 inhibitor), and it is therefore recommended that brexpiprazole dosages be reduced when brexpiprazole is coadministered with known CYP2D6 and CYP3A4 inhibitors. Plasma levels of brexpiprazole were decreased when the drug was coadministered with rifampin (a CYP3A4 inducer) during in vivo studies, and it is therefore recommended that brexpiprazole dosages be increased when brexpiprazole is coadministered with known CYP3A4 inducers. Brexpiprazole has limited induction or inhibition of other CYP enzymes, according to multiple in vivo studies (Otsuka Pharmaceutical 2023).

Conclusion

Aripiprazole was the first agent that was not a full D_2 receptor antagonist to show rapid and sustained antipsychotic activity, and it may be considered the first partial dopamine agonist combined with 5-HT-stabilizing properties. Short-term and long-term clinical trials in adult and pediatric patients with schizophrenia and bipolar I disorder have demonstrated that aripiprazole combines sustained antipsychotic and mood-stabilizing efficacy with an excellent safety and tolerability profile. Additional augmentation trials have confirmed the utility of aripiprazole in alleviating depressive symptoms for patients with MDD who have not achieved adequate symptom relief with antidepressants alone. The efficacy and safety of aripiprazole have also been established in child and adolescent populations for the management of irritability in autism spectrum disorders and Tourette's disorder. Aripiprazole is now also available in two different long-term depot injectable formulations for the management of schizophrenia in adults.

Brexpiprazole shares multiple traits with aripiprazole, including partial dopamine agonism and 5-HT-stabilizing properties. However, brexpiprazole has lower intrinsic dopaminergic activity than does aripiprazole, which may indicate an even more favorable side-effect profile relative to the well-tolerated older drug. Several short-term clinical trials of adult patients with acute schizophrenia or with a lack of response to previous therapy for MDD have confirmed the efficacy and tolerability of this newly established atypical antipsychotic. A variety of clinical trials with brexpiprazole targeting different treatment populations, including head-to-head trials with other antipsychotics to further establish clinical efficacy, have been initiated or are ongoing.

In general, both aripiprazole and brexpiprazole are associated with low incidences of EPS, QTc interval prolongation, prolactin elevation, weight gain, and disturbance

of glucose or lipid metabolism. The combination of efficacy, safety, and tolerability suggests that both aripiprazole and brexpiprazole are important options for the acute treatment of schizophrenia and for the adjunctive treatment of MDD. Aripiprazole additionally is an important treatment option for bipolar I disorder, irritability in autism spectrum disorder, and Tourette's disorder as well as for long-term management of schizophrenia.

CHAPTER 31

Ziprasidone and Asenapine

John W. Newcomer, M.D.
Jared Lipsey, B.Sc.
Martin T. Strassnig, M.D.
Leslie Citrome, M.D., M.P.H.

This chapter reviews background information, pharmacological profiles, clinical indications, adverse events, and other considerations for two atypical, or second-generation, antipsychotic agents, ziprasidone and asenapine. These medications each offer unique potential benefits and overall favorable safety profiles that led to their regulatory approval in the United States and multiple other countries.

Ziprasidone

History and Discovery

Ziprasidone (CP-88059) is an atypical, or second-generation, antipsychotic agent that has activity for treating symptoms of schizophrenia and schizoaffective disorder and for treating mania and mixed states in bipolar disorder, with limited adverse extrapyramidal, sedative, anticholinergic, and cardiometabolic effects. First approved in 2001, this antipsychotic was initially part of a new drug application for the treatment of psychotic disorders submitted to the FDA in 1997. Because of concerns regarding an increase in the mean duration of the QT interval, an electrocardiographic measure of the ventricular depolarization and repolarization phases of cardiac conduction, the application was not initially approved. Further studies, designed in collaboration with the FDA, quantified the limited extent of the QTc interval lengthening effect seen with ziprasidone compared with that seen with other agents in wide use; these studies established the safety of ziprasidone with respect to cardiac conduction and established a benchmark for the approach to evaluating drug effects on the QT interval that has subsequently been applied to other agents evaluated by the FDA. Ziprasidone received regulatory approval in the United States in 2001 and is now available in more than 90 countries. Ziprasidone is currently available as oral capsules (20, 40, 60, and 80 mg) and as an intramuscular injection (20-mg single-dose vial).

Structure-Activity Relations and Pharmacological Profile

Ziprasidone, or 5-{2-[4-(1,2-benzisothiazol-3-yl)-1-piperazinyl]ethyl}-6-chloro-1,3-dihydro-2H-indol-2-one, is a novel benzisothiazolyl piperazine antipsychotic (Figure 31-1).

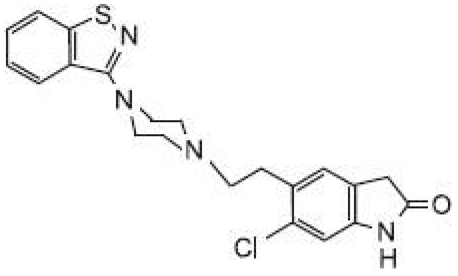

FIGURE 31-1. Chemical structure of ziprasidone.

Ziprasidone is a potent antagonist at dopamine type 2 (D_2) receptors with inverse agonist activity at serotonin type 2A (5-HT_{2A}) receptors. D_2 receptor antagonism is thought to be a key mechanism explaining its efficacy for the treatment of psychotic symptoms (Kapur and Remington 2001); in vivo PET analysis has shown that occupancy of at least 60% of striatal D_2 receptors, predictive of clinical antipsychotic response, is observed at ziprasidone plasma concentrations attained with dosages [?] 120 mg/day (Mamo *et al.* 2004). However, ziprasidone also has inverse agonist activity at 5-HT_{2A} receptors, an effect that can disinhibit dopamine neurotransmission in the nigrostriatal, mesocortical, and tuberoinfundibular pathways (Kapur and Remington 2001; Schmidt *et al.* 2001). This effect suggests a mechanism for reduced liability for extrapyramidal side effects (EPS) compared with antipsychotics with unopposed D_2 receptor antagonism. Ziprasidone's relatively high in vitro 5-HT_{2A}/D_2 receptor affinity ratio, compared with that of many other second-generation antipsychotics (SGAs), predicts a low liability for EPS and potential benefits for negative symptoms (Altar *et al.* 1986).

Ziprasidone exhibits antagonist activity at serotonin type 1D (5-HT_{1D}) and type 2C (5-HT_{2C}) receptors and unusual (among SGAs) agonist activity at serotonin type 1A (5-HT_{1A}) receptors (DeLeon *et al.* 2004; Schmidt *et al.* 2001). Ziprasidone's 5-HT_{1A} affinity is comparable to that of buspirone, an agent with antidepressant and anxiolytic properties (Diaz-Mataix *et al.* 2005; Ichikawa *et al.* 2001; Mazei *et al.* 2002; Millan 2000; Rollema *et al.* 2000; Sumiyoshi *et al.* 2003; Tauscher *et al.* 2002). Potent antagonism at 5-HT_{1D} receptors has been proposed to mediate antidepressant and anxiolytic effects (Briley and Moret 1993; Zorn *et al.* 1998). Blockade of 5-HT_{2C} receptors disinhibits both dopamine and norepinephrine neurons in the cortex, an effect that could contribute to improvements in cognition and affect (Bymaster *et al.* 2002; Mazei *et al.* 2002; Stahl 2003). Although 5-HT_{2C} receptor antagonist activity might predict weight gain liability according to a 5-HT_{2C} knockout mouse model of obesity (Tecott *et al.* 1995), clinically significant predictive effects of 5-HT_{2C} receptor antagonist activity on the relative risk for weight gain associated with antipsychotic drugs have not been reliably detected (Kroeze *et al.* 2003), and the risk for weight gain associated with ziprasidone is observed to be among the lowest of available antipsychotics (Allison *et al.* 1999).

Another important feature of ziprasidone is its relatively high affinity for serotonin and norepinephrine transporters (Seeger *et al.* 1995; Tatsumi *et al.* 1999). In vitro, ziprasidone demonstrates dose-dependent reuptake inhibition of serotonin and norepinephrine transport, with effects ranging up to those of imipramine and amitriptyline (Schmidt *et al.* 2001). In vivo, the clinical significance of ziprasidone's monoaminergic reuptake inhibition may be limited by plasma protein binding or may be clinically relevant only at daily dosages higher than those approved.

Ziprasidone has low affinity for histaminergic type 1 (H_1), muscarinic type 1 (M_1), and a_1-noradrenergic receptors. Among the biogenic amine receptors, H_1 receptor antagonist activity may be the largest predictor of weight gain liability (Kroeze *et al.* 2003). H_1 antagonist activity also predicts sedative effects, which are undesirable for patients aiming to maximize cognitive performance and social, occupational, and community engagement. Low affinity for a_1-adrenergic receptors predicts a lower likelihood of orthostatic hypotension and sedation with ziprasidone than with commonly used antipsychotics with potent a_1-adrenergic receptor antagonist activity. Low affinity for M_1 receptors predicts a low risk for anticholinergic side effects.

Evidence from randomized clinical trials, as well as PET results noted previously, suggests that ziprasidone target dosages should be higher than those originally recommended for schizophrenia. In the United States, it was initially recommended that ziprasidone treatment in patients with schizophrenia be initiated at a dosage of 20 mg bid, with the dosage then titrated at intervals of no less than 2 days to a maximum of 80 mg bid (Pfizer Inc. 2020). In contrast, subsequent FDA approval of ziprasidone for the treatment of bipolar mania included a recommendation that treatment be initiated at 40 mg bid with a more rapid titration; on the second day of treatment, the dosage might be increased to 60 or 80 mg bid, with subsequent adjustment based on tolerability and efficacy within a 40-to 80-mg bid range. Ziprasidone dosages of 120-160 mg/day are observed to be more effective than lower dosages in the treatment of acute schizophrenia

(Kane 2003b) and bipolar disorder in adults (Citrome *et al.* 2009b) and are associated with lower rates of medication discontinuation (Citrome *et al.* 2009c). Reported clinical experience with ziprasidone has suggested the need for dosages greater than 160 mg/day in selected patients (Citrome *et al.* 2009a; Harvey and Bowie 2005; Nemeroff *et al.* 2005). However, a dosage of 320 mg/day, twice the maximal recommended dosage of 160 mg/day, did not lead to any additional symptom improvement in a small 8-week placebo-controlled trial compared with a dosage of 160 mg/day, and plasma drug levels were similar between the two dosages at the end of the study period. There was a trend toward increased diastolic blood pressure, more negative symptoms, and greater QTc prolongation at 320 mg/day (Goff *et al.* 2013).

Pharmacokinetics and Drug-Drug Interactions

On the basis of evidence of enhanced absorption of ziprasidone in the presence of food, it is recommended that oral ziprasidone be taken with meals of at least 500 kcal to avoid a substantial reduction in drug absorption (Gandelman *et al.* 2009) that cannot be effectively compensated for by increasing the dosage (Citrome 2009b). Administration with food increases absorption by more than 50%, giving ziprasidone an oral bioavailability of approximately 60% (Pfizer Inc. 2020). The maximum plasma concentration (C_{max}) is achieved within 3.7-4.7 hours and reaches 45-139 mg/L in healthy volunteers receiving 20-60 mg bid, and steady-state serum concentrations occur within 1-3 days of twice-daily dosing (Hamelin *et al.* 1998; Miceli *et al.* 2000c). In contrast to oral administration, intramuscular administration of ziprasidone results in 100% bioavailability. A therapeutic plasma level is reached within 10 minutes, and C_{max} is achieved within 30 minutes of administration of a 20-mg dose (Pfizer Inc. 2020).

The mean apparent volume of distribution of ziprasidone is 1.5 L/kg (Pfizer Inc. 2020), which is lower than that of many other antipsychotic drugs. Given the greater potential for unwanted interactions with various intracellular targets that has been observed with lipophilic drugs having a high volume of distribution (Dwyer *et al.* 1999), this may be a favorable attribute of ziprasidone and other similar compounds. Ziprasidone is more than 99% bound to plasma proteins.

Pharmacokinetic studies have examined ziprasidone bioavailability under fasting conditions and after the consumption of food with varying caloric and fat compositions to better understand effects of food intake on drug availability (Gandelman *et al.* 2009; Lombardo *et al.* 2007). In an open-label, nonrandomized, six-way crossover study, healthy adults received single doses of ziprasidone under fasting conditions and then under fed conditions with a standard meal of 800-1,000 calories. Dose-proportional increases in ziprasidone area under the curve (AUC) and C_{max} were observed under fed but not fasting conditions. C_{max} was significantly higher in fed states than in fasting states at doses of 40 mg (63% higher) and 80 mg (97% higher). Results from two additional open-label crossover studies further clarified the factors regulating drug bioavailability (Gandelman *et al.* 2009; Lombardo *et al.* 2007). They indicated that 1) medium-calorie meals (500 calories) are associated with ziprasidone exposure close to the exposure that can be achieved with high-calorie meals (1,000 calories) and nearly twice the exposure observed under fasting conditions, and 2) absorption is not significantly influenced by the fat content of the meal.

Ziprasidone is extensively metabolized, with a mean terminal elimination half-life of approximately 7 hours after oral administration within the recommended clinical dosage range (Pfizer Inc. 2020). The elimination half-life of intramuscular ziprasidone is less than 3 hours with a single dose (Brook *et al.* 2000). Ziprasidone is cleared primarily via three metabolic pathways to yield four major circulating metabolites. Elimination occurs primarily through hepatic metabolism, with less than one-third of metabolic clearance mediated via cytochrome P450 (CYP)-catalyzed oxidation and approximately two-thirds via reduction of the parent compound by aldehyde oxidase to dihydroziprasidone, which then undergoes *S*-methylation. The literature reports no commonly encountered clinically significant pharmacological inhibitors of aldehyde oxidase, which suggests limited real-world potential for drug-drug interactions that would alter the clinical activity of ziprasidone (Obach *et al.* 2004).

Additional secondary metabolic pathways include *N*-dealkylation (via CYP3A4 and CYP1A2) and direct *S*-oxidation (via CYP3A4) (Beedham *et al.* 2003; Prakash *et al.* 2000). *S*-methyl-dihydroziprasidone is the only active metabolite, with lower D_2 receptor affinity and no significant binding to H_1, M_1, or a_1- and a_2-adrenergic receptors. A small amount of the parent compound is excreted unchanged in the urine (< 1%) and feces (< 4%).

There are no clinically significant age-or sex-related differences in the pharmacokinetics of oral ziprasidone (Pfizer Inc. 2020). Hepatic impairment might be expected to increase the AUC. A multiple-dose study (Everson *et al.* 2000) comparing subjects with clinically significant (Child-Pugh class A and B) cirrhosis and healthy control subjects indicated that 12 hours after administration of ziprasidone, the AUC was 13% and 34% greater in subjects with Child-Pugh class A and B cirrhosis, respectively, than in matched control subjects, which suggests that dosage adjustments are generally not mandatory for patients with hepatic impairment. Impairment in renal function is unlikely to significantly alter the pharmacokinetics of oral ziprasidone, which suggests that ziprasidone would not be removed by hemodialysis (Pfizer Inc. 2020). Intramuscular ziprasidone has not been systematically evaluated in the elderly or in patients with hepatic or renal impairment. Intramuscular ziprasidone contains a cyclodextrin excipient that is cleared by renal filtration; thus, it should be administered with caution to patients with impaired renal function (Pfizer Inc. 2020).

A study of in vitro enzyme inhibition (Pfizer Inc. 2020) indicated that ziprasidone has very little inhibitory effect on CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4 and is thus unlikely to interfere with the metabolism of other medications that rely on these enzymes for clearance. In vivo studies have indicated that ziprasidone has no effect on the pharmacokinetics of lithium, estrogen, progesterone, or dextromethorphan (Pfizer Inc. 2020). Less than one-third of ziprasidone clearance is mediated by CYP-catalyzed oxidation, and because of this one would not anticipate a substantial change in ziprasidone AUC during coadministration with CYP3A4 inhibitors or inducers. Aldehyde oxidase-mediated reduction constitutes the primary metabolic pathway for ziprasidone. As also noted previously, currently no clinically significant pharmacological inhibitors of aldehyde oxidase are commonly encountered (Obach *et al.* 2004). Consistent with this prediction, coadministration of ziprasidone with ketoconazole, a potent CYP3A4 inhibitor, results in only modest increases in ziprasidone AUC (33%) and C_{max} (34%) (Miceli *et al.* 2000b), whereas coadministration with carbamazepine, an inducer of CYP3A4, results in modest reductions in ziprasidone AUC (44%) and C_{max} (39%) (Miceli *et al.* 2000a). Coadministration with CYP2D6 inhibitors has no effect on ziprasidone plasma levels. Coadministration of ziprasidone with lithium results in no significant change in steady-state lithium levels (Apseloff *et al.* 2000), and commonly used antacids and cimetidine do not significantly alter ziprasidone pharmacokinetics (Pfizer Inc. 2020).

Indications and Efficacy

Schizophrenia and Schizoaffective Disorder

Ziprasidone is approved in the United States for short-term and maintenance treatment of schizophrenia. Its efficacy in the treatment of hospitalized patients with acute schizophrenia or schizoaffective disorder was demonstrated in a series of double-blind, placebo-controlled

trials of 4-6 weeks' duration (Daniel *et al.* 1999; Kane 2003b; Keck *et al.* 1998, 2001). Additional short-term (4-to 8-week) randomized, double-blind treatment studies using active antipsychotic comparator agents indicated that ziprasidone has efficacy comparable to that of haloperidol, risperidone, and olanzapine for the treatment of positive symptoms and overall psychopathology (Addington *et al.* 2004; Goff *et al.* 1998; Simpson *et al.* 2004a). In a pooled analysis of four short-term placebo-controlled trials and three active comparator trials, Murray *et al.* (2004) demonstrated that ziprasidone dosages of at least 120 mg/day, in comparison with lower dosages, are associated with a more rapid and favorable response in overall psychopathology as well as a lower discontinuation rate due to inadequate clinical response, which suggests the importance of rapid titration to at least 120 mg/day (Kane 2003b; McCue *et al.* 2006).

Suboptimal dosing, inadequate titration regimens, and failure to administer ziprasidone with food may have negatively affected its performance in some clinical trials. Some clinical trials included efficacy analyses of dosages that would now be considered suboptimal (i.e., < 120 mg/day), whereas other studies used prolonged titration of ziprasidone, with a therapeutic dosage not reached until 1 week or more into the study. Clinical trials conducted before the release of pharmacokinetic data by Lombardo *et al.* (2007) may not have been designed to ensure that ziprasidone was administered with food for optimal oral absorption.

Ziprasidone has also been studied for the treatment of early psychosis and schizophrenia. In a study by Johnsen *et al.* (2010), patients admitted to an emergency ward with early psychosis were consecutively randomly assigned to receive one of several different SGAs: ziprasidone, olanzapine, quetiapine, or risperidone. No clinically significant differences in the effectiveness of the tested antipsychotics emerged after a 2-year follow-up period. Crespo-Facorro *et al.* (2013, 2014), in a 12-week prospective, open-label, randomized trial followed by a year-long extension period comparing quetiapine, aripiprazole, and ziprasidone for the treatment of first-episode psychosis, found significantly greater discontinuation rates with quetiapine than with aripiprazole or ziprasidone, owing to insufficient efficacy of quetiapine and comparable efficacy of the other two tested agents.

The maintenance efficacy of ziprasidone in treating schizophrenia and schizoaffective disorder was studied in a series of double-blind and open-label extension trials (Arato *et al.* 2002; Hirsch *et al.* 2002; Kane 2003a; Schooler 2003; Simpson *et al.* 2002, 2004b). These studies indicated that long-term therapy with ziprasidone maintains clinical response and is effective in preventing relapse.

In two maintenance-of-effect studies, patients with schizophrenia or schizoaffective disorder who had previously demonstrated acute response to treatment (defined as a [?] 20% decrease in Positive and Negative Syndrome Scale [PANSS] total score and a Clinical Global Impression [CGI] Scale score of [?] 2) were randomly assigned to receive either ziprasidone or a comparator antipsychotic agent for at least 26 weeks (Addington *et al.* 2009; Schooler 2003; Simpson *et al.* 2002, 2005). In both of these studies, the ziprasidone treatment groups demonstrated significant improvements from baseline in overall psychopathology, as measured by mean changes in symptom ratings using PANSS total, PANSS-Negative subscale, Brief Psychiatric Rating Scale--Depression Factor (BPRS-D), and CGI-Severity (CGI-S) scores. These improvements were comparable to those seen in the olanzapine (Simpson *et al.* 2005) and risperidone (Addington *et al.* 2009) treatment groups.

To evaluate relapse prevention, the Ziprasidone Extended Use in Schizophrenia (ZEUS) study enrolled stable inpatients with chronic schizophrenia and randomly assigned participants to 1 year of treatment with ziprasidone 40 mg/day (n = 72), 80 mg/day (n = 68), or 160 mg/day (n = 67) or placebo (n = 71), with a planned primary Kaplan-Meier analysis of time to relapse (Arato *et al.* 2002). In this study, all three dosages of ziprasidone were superior to placebo in the prevention of relapse.

A number of long-term double-blind trials designed to examine the efficacy of ziprasidone in symptomatic patients with schizophrenia have been performed (Breier *et al.* 2005; Hirsch *et al.* 2002; Kinon *et al.* 2006; Simpson *et al.* 2004a, 2005). Hirsch *et al.* (2002) compared the efficacy of ziprasidone (n = 148) and haloperidol (n = 153) in a 28-week double-blind trial of stable outpatients with schizophrenia with prominent negative symptoms. In this study, ziprasidone and haloperidol were similarly efficacious in reducing overall psychopathology, with an advantage for ziprasidone in the percentage of patients classified as negative symptom responders. Breier *et al.* (2005) conducted a 28-week study of ziprasidone and olanzapine in outpatients as well as inpatients (N = 548) with active symptoms. In this study, olanzapine treatment was associated with greater improvement from baseline in total psychopathology scores (PANSS total score, the primary efficacy measure) compared with ziprasidone and a higher rate of criterion-level response to treatment. Simpson *et al.* (2004a) conducted a 6-week double-blind, parallel-design, flexible-dose comparison (N = 269) of ziprasidone (n = 136) and olanzapine (n = 133) in which patients who showed at least minimal response (CGI-Improvement [CGI-I] score [?] 2 or [?] 20% reduction in the PANSS total score) were enrolled in a 6-month double-blind continuation trial (Simpson *et al.* 2005). In both 6-week and 6-month analyses, no differences between the treatment groups were detected on any primary (e.g., BPRS total score, CGI-S) or secondary (e.g., PANSS total score, CGI-I) measures.

Potkin *et al.* (2009) compared the effects of ziprasidone and haloperidol in a 196-week double-blind study using the Andreasen criteria for remission (Andreasen *et al.* 2005) by longitudinal analysis. During the initial 40-week study, no differences in PANSS or Global Assessment of Functioning (GAF) Scale score changes between the two antipsychotics compared emerged. In a subsequent 3-year extension study, ziprasidone-treated subjects were more likely to achieve remission (51%) compared with haloperidol-treated subjects (40%). The PANSS total and GAF score trajectories favored the higher 80-160 mg/day ziprasidone dosage as opposed to lower dosages, and the superior outcome for ziprasidone versus haloperidol may have been due in part to tolerability and adherence advantages.

There have been a number of effectiveness studies involving ziprasidone and using various definitions of *effectiveness*. Two are noted here. The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) studies, funded by the National Institute of Mental Health, included a long-term, double-blind, randomized study of patients with schizophrenia (*N* = 1,493; Lieberman *et al.* 2005). Phase 1 of the CATIE schizophrenia study compared ziprasidone, olanzapine, quetiapine, risperidone, and perphenazine on a primary endpoint of time to discontinuation for lack of efficacy or for any cause. Because of the timing of its FDA approval, ziprasidone was added to the study after enrollment had begun for all other treatment arms; this resulted in a smaller sample size for the ziprasidone treatment arm and some limitations regarding conclusions about ziprasidone in phase 1 of the study.

The primary analysis for the phase 1 study detected significant differences in time to discontinuation across the treatment groups overall. The longest time to discontinuation was in the olanzapine group. In the total study sample, no significant differences were seen in the time to discontinuation between the ziprasidone and olanzapine treatment groups or between the ziprasidone group and the other antipsychotic treatment groups. However, fewer patients who entered the CATIE schizophrenia study were currently (i.e., prior to study entry) taking the relatively newly available ziprasidone compared with the number of patients taking the other antipsychotic medications in the trial. Supplemental analysis of phase 1 CATIE data by Essock *et al.* (2006) indicated the overall importance, in terms of subsequent discontinuation rates, of whether randomized subjects were switching medications or whether the study randomization allowed them to continue receiving their prior treatment. A significantly higher rate of subsequent discontinuation was observed in patients who actually made a medication switch compared with those who were randomly assigned to stay with the same medication they had been taking prior to the trial. This effect of switching medications therefore favored treatment arms with a larger percentage of nonswitchers (i.e., olanzapine and risperidone recipients in the CATIE phase 1 study). In a reanalysis of phase 1 CATIE data that excluded those patients randomly assigned to continue taking the antipsychotic they were already taking at baseline, Essock *et al.* (2006) found that differences between rates of discontinuation in the ziprasidone group and in the other antipsychotic groups were attenuated, and no statistically significant differences in the primary outcome measure were observed for any agent.

The Ziprasidone Experience in Schizophrenia in Germany/Austria (ZEISIG) study investigated the effectiveness of ziprasidone as measured by discontinuation rates and mean change in the BPRS total score in moderately ill and reasonably stable patients (*N* = 276) with schizophrenia or schizoaffective disorder (Kudla *et al.* 2007). Approximately 60% of subjects discontinued ziprasidone prematurely, most within the first 4 weeks of study treatment. In this study, ziprasidone use was initiated at a dosage of 40 mg/day. The relatively high rate of discontinuation may be explained in part by the planned dosing strategy.

Bipolar Disorder

Ziprasidone has received regulatory approval (e.g., from the FDA) as a monotherapy for the acute treatment of manic or mixed episodes in bipolar

I disorder, with acute efficacy demonstrated in two double-blind, placebo-controlled trials, each 3 weeks in duration, in patients with bipolar I disorder (Keck *et al.* 2003b; Potkin *et al.* 2005). In both studies, the onset of action was rapid (within 48 hours) and sustained through 3 weeks of treatment in patients with bipolar mania or bipolar mixed states, with or without psychotic symptoms. At endpoint, approximately half of the treated patients from both studies had symptom improvement that met response criteria for mania ([?] 50% reduction in Mania Rating Scale [MRS] scores).

A number of placebo-controlled trials evaluating the efficacy of short-term monotherapy with various antipsychotics, including haloperidol, ziprasidone, olanzapine, risperidone, quetiapine, and aripiprazole, have demonstrated comparable improvement in symptoms of mania (Bowden *et al.* 2005; Hirschfeld *et al.* 2004; Keck *et al.* 2003a, 2003b; Khanna *et al.* 2005; McIntyre *et al.* 2005; McQuade *et al.* 2003; Potkin *et al.* 2005; Sachs *et al.* 2006; Smulevich *et al.* 2005; Tohen *et al.* 1999, 2000; Vieta *et al.* 2010; Weisler *et al.* 2003). Regulatory approvals for individual agents have supported the efficacy and safety of a number of individual antipsychotics for acute treatment.

Mixed episodes (dysphoric mania) represent a common and often difficult-to-treat subset of bipolar mania that can be associated with significant depressive symptoms. Pooled data from a post hoc analysis of two similarly designed 3-week placebo-controlled trials (Stahl *et al.* 2010) in patients with acute bipolar mania indicated that ziprasidone significantly improved both depressive symptoms and symptoms of manic mood in patients with dysphoric mania. A meta-analysis by Muralidharan *et al.* (2013) supported the conclusion that some SGAs, including ziprasidone, are effective for the treatment of mixed states of bipolar disorder with predominant manic symptoms.

Two 52-week open-label extension studies supported the safety, tolerability, and sustained efficacy of ziprasidone as maintenance treatment for bipolar I disorder as adjunctive therapy to lithium or valproate (Keck *et al.* 2004, 2009; Weisler *et al.* 2004). The FDA has approved this indication. Keck *et al.* (2004) reported that treatment with ziprasidone (*n* = 127; mean dosage 123 mg/day) was associated with significantly lower MRS and CGI-S scores compared with baseline, beginning as early as the first week. Overall, improvements in manic symptoms achieved during acute treatment continued to consolidate during maintenance treatment with ziprasidone. During 52 weeks of treatment, only 6% of patients discontinued ziprasidone use because of a relapse of mania. Similarly, only 4% of patients discontinued because of a clinical switch into depression. An important caveat regarding these results is that a high rate of attrition was observed by the end of 1 year, which is consistent with long-term studies involving other SGAs but still limits full interpretation of the results. Comparable results were observed in a separate extension study of adjunctive ziprasidone therapy (mean dosage 92.6 mg/day) by Weisler *et al.* (2004); this study reported a mean improvement from baseline in MRS scores at all points throughout the study (Patel and Keck 2006). Finally, subjects with DSM-IV (American Psychiatric Association 1994) bipolar I disorder who achieved 8 or more consecutive weeks of stability with open-label ziprasidone (80-160 mg/day) adjunctive to lithium or valproate were randomly assigned in a 6-month double-blind maintenance period to receive ziprasidone plus mood stabilizer or placebo plus mood stabilizer. The time to intervention for a mood episode and the time to discontinuation for any reason were significantly longer for ziprasidone compared with placebo (Bowden *et al.* 2010), which indicates that ziprasidone is useful in combination with a classic mood stabilizer for maintenance of euthymia in bipolar disorder.

Treatment-Resistant Depression

A randomized, double-blind, placebo-controlled study, as well as a series of uncontrolled studies, has stimulated interest in the efficacy of ziprasidone for treating depression, especially treatment-resistant depression (Barbee *et al.* 2004; Jarema 2007; Papakostas *et al.* 2004, 2015). Papakostas *et al.* (2004) reported the results of a small study of 20 patients with major depressive disorder resistant to treatment with selective serotonin reuptake inhibitors. Open-label treatment with ziprasidone for 6 weeks, adjunctive to ongoing treatment with selective serotonin reuptake inhibitors, was evaluated with an intent-to-treat analysis that identified 10 treatment responders (defined as subjects with a [?] 50% decrease in depressive symptoms as measured by the 17-item version of the Hamilton Rating Scale for Depression [Ham-D-17]). In order to further evaluate these effects, a randomized, double-blind, placebo-controlled trial was conducted to compare adjunctive ziprasidone with adjunctive placebo among 139 adult outpatients with major depressive disorder who had not responded to an 8-week open-label trial of escitalopram alone (Papakostas *et al.* 2015). Compared with the patients who were randomly assigned to receive adjunctive placebo, those assigned to receive adjunctive ziprasidone (mean dosage 98 mg/day; SD = 40) with escitalopram demonstrated significantly greater rates of clinical response as well as significantly greater improvement in the Ham-D-17 total score and the Hamilton Anxiety Scale score. Ziprasidone has also been tested in non-treatment-resistant depression. A 12-week randomized, double-blind, placebo-controlled sequential parallel comparison trial of ziprasidone as monotherapy for major depressive disorder in 120 outpatients with depression conducted by Papakostas *et al.* (2012) showed no significant efficacy for ziprasidone compared with placebo. The authors suggested that a larger trial may be required to detect significant differences.

Agitation

The efficacy of intramuscular ziprasidone for the treatment of acutely agitated patients with schizophrenia was demonstrated in two randomized double-blind trials (2 mg IM vs. 10 mg or 20 mg IM, respectively, with up to three more doses allowed as needed at 4-hour or 2-hour intervals, respectively), which led to regulatory approval by the FDA (Daniel *et al.* 2001; Lesem *et al.* 2001). Treatment with single 10-or 20-mg doses leads to rapid reductions in symptom severity, with most patients having remission of agitation within 1 hour of dosing. Treatment with intramuscular ziprasidone is associated with a relatively low rate of concomitant benzodiazepine use (< 20%) and may be better tolerated than treatment with haloperidol (Zhang *et al.* 2013). Sequential use of intramuscular ziprasidone followed by oral ziprasidone for the treatment of acute psychotic agitation demonstrated superior efficacy, compared with sequential use of intramuscular and oral haloperidol, in two 7-day randomized open-label trials (Brook *et al.* 2000; Swift *et al.* 1998) as well as in a 6-week randomized, single-blind, flexible-dose study (Brook *et al.* 2005). Clinical improvement occurred more rapidly with ziprasidone than with haloperidol in one study and as quickly as 30 minutes after the first intramuscular administration of ziprasidone (Swift *et al.* 1998). Cumulative data from these studies indicate that intramuscular ziprasidone can rapidly control agitation and psychotic symptoms and can provide greater mean improvements in acute agitation than those seen with intramuscular haloperidol (e.g., greater mean improvements in the BPRS total score, agitation, and the CGI-S score [Brook 2003]).

Use in Pediatric Populations

Ziprasidone is not approved by the FDA for use in pediatric patients in the United States. Its use has been evaluated in children and adolescents (ages 10-17 years) experiencing manic or mixed episodes associated with bipolar disorder (Kuehn 2009). In the European Union (European Medicines Agency), ziprasidone has been approved for the treatment of bipolar disorder (mania) in pediatric patients ages 10-17 years. Results have been reported from randomized controlled trials (RCTs) of ziprasidone in children and adolescents (ages 10-17 years) with bipolar disorder

(Versavel *et al.* 2005) and with bipolar disorder, schizophrenia, or schizoaffective disorder (DelBello *et al.* 2008). In one study, treatment with ziprasidone was associated with improvement in mania and overall psychopathology (Versavel *et al.* 2005). Another study focused on safety and did not report any unexpected tolerability findings in this age group for a starting dosage of 20 mg/day titrated to between 80 mg/day and 160 mg/day over 1-2 weeks for clinically determined optimal dosing (DelBello *et al.* 2008). Finally, a 4-week acute randomized, placebo-controlled multicenter trial, followed by a 26-week open-label extension study, in pediatric patients with bipolar disorder (ages 10-17 years) showed benefits of ziprasidone and a benign short-term side-effect profile (Findling *et al.* 2013a). In a study of pediatric schizophrenia using a 6-week randomized (2:1), double-blind, placebo-controlled design, ziprasidone did not separate from placebo (Findling *et al.* 2013b).

Side Effects and Toxicology

Ziprasidone has a favorable tolerability profile according to both short-and long-term clinical trials (Daniel 2003). The four most common treatment-related adverse events associated with oral ziprasidone in short-term premarketing placebo-controlled trials for schizophrenia were somnolence (14%), EPS (14%), nausea (10%), and constipation (9%) (Pfizer Inc. 2020). In subsequent clinical trials, treatment with ziprasidone was associated with a low occurrence of adverse events, most of which were considered mild to moderate in severity (Arango *et al.* 2007; Arato *et al.* 2002; Lieberman 2007; Nemeroff *et al.* 2005; Weiden *et al.* 2002, 2003b). In addition to the full U.S. prescribing information, which contains a comprehensive list of potential adverse events (Pfizer Inc. 2020), published case reports offer accounts of various rare adverse events that may be associated with the use of ziprasidone (Akkaya *et al.* 2006; Kaufman *et al.* 2006; Miodownik *et al.* 2005; Murty *et al.* 2002; Villanueva *et al.* 2006).

Intramuscular ziprasidone shows a favorable tolerability profile similar to that of oral ziprasidone. In premarketing trials of intramuscular ziprasidone, the most common side effects (those with an incidence of > 5% and an incidence greater than that seen in placebo recipients) were somnolence (20%), headache (13%), and nausea (12%) (Pfizer Inc. 2020). Pooled data from clinical trials of intramuscular ziprasidone indicated that most treatment-related adverse events were mild to moderate in severity, with the most common side effects being headache, nausea, dizziness, insomnia, anxiety, and pain at the injection site (Daniel 2003; Zimbroff *et al.* 2002).

Ziprasidone was previously considered a Category C drug in pregnancy. In December 2014, the FDA published a final rule on labeling for pregnancy and lactation that removed the letter category labeling and required drug labels to be updated when new information becomes available (U.S. Food and Drug Administration 2021). Although some specific developmental effects have been noted in animal studies at dosages ranging from 0.5 to 8.0 times the maximal recommended human dosage (Pfizer Inc. 2020), there is as yet no similar emerging evidence of such effects in humans. The reader is advised to consult the current U.S. prescribing information for a detailed list of potential adverse drug effects identified in the regulatory approval process and postmarketing surveillance.

In 2005, the FDA mandated the addition of a black box warning in the U.S. prescribing information regarding an increased risk of mortality associated with the use of both SGAs and first-generation antipsychotics (FGAs) in elderly patients with dementia-related psychosis. Observed causes of death have been varied, and the mechanism of any drug effect in schizophrenia remains uncertain. In particular, it remains unclear to what extent these uncontrolled observations of increased mortality are due to specific drug effects or to the advanced medical risk characteristics of patients with dementia or delirium who tend to receive these medications (Farber *et al.* 2000; Rochon *et al.* 2008). A retrospective cohort study among older adults exposed to antipsychotics did not find increased mortality associated with ziprasidone, in contrast with haloperidol, olanzapine, and risperidone (Gerhard *et al.* 2014). Retrospective analysis of intramuscular use of ziprasidone, olanzapine, or haloperidol in large matched cohorts of hospitalized patients, for example, did not indicate significant differences in mortality rates among the three cohorts (Holdridge *et al.* 2010).

In 2014, the FDA issued a warning that ziprasidone is one of more than 50 medications associated with a rare condition called drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome. This potentially life-threatening hypersensitivity reaction presents as a skin rash with fever, eosinophilia, lymphadenopathy, and multiorgan inflammation. Patients who develop this constellation of symptoms during treatment with ziprasidone should be evaluated for possible DRESS syndrome, and if that syndrome is suspected, their medication should be discontinued (Cacoub *et al.* 2011).

Treatment with ziprasidone is associated with a relatively low risk of clinically significant increases in body weight. An analysis of available studies with this agent and other antipsychotics, both FGAs and SGAs (Allison *et al.* 1999), estimated a mean 0.04-kg weight gain over a 10-week treatment period with ziprasidone and identified ziprasidone as having one of the lowest estimated effects on body weight of the agents analyzed. In a 6-week RCT in patients with acute exacerbations of schizophrenia or schizoaffective disorder, treatment with ziprasidone 80 mg/day produced a median increase in body weight of 1 kg, compared with no change in median weight with ziprasidone 160 mg/day or placebo (Daniel *et al.* 1999). In a 28-week study of outpatients with schizophrenia, mean changes in body weight from baseline to endpoint were similar during treatment with ziprasidone (+ 0.31 kg) and haloperidol (+ 0.22 kg) (Hirsch *et al.* 2002). In a 28-week study comparing the effects of ziprasidone and olanzapine, ziprasidone-treated patients experienced a small decrease in mean body weight ([?] 1.12 kg) from baseline, compared with a statistically and clinically different 3.06-kg mean increase in body weight observed with olanzapine treatment (Hardy *et al.* 2003; Kinon *et al.* 2006). Reductions in body weight were also associated with ziprasidone treatment in the 1-year ZEUS study of patients with chronic, stable schizophrenia (Arato *et al.* 2002); this study reported mean decreases from baseline of 2.7 kg, 3.2 kg, and 2.9 kg with 40 mg/day, 80 mg/day, and 160 mg/day dosages of ziprasidone, respectively, compared with a 3.6-kg decrease observed with placebo treatment. Results from the phase 1 and phase 2 CATIE studies provided further confirmation that treatment with ziprasidone has a low intrinsic risk for producing clinically significant weight gain, with 6%-7% of ziprasidone recipients demonstrating a 7% or greater increase from baseline in body weight compared with, for example, 27%-30% of olanzapine recipients (Lieberman 2007; Stroup *et al.* 2006). In the phase 1 CATIE study, ziprasidone treatment was associated with a mean reduction in body weight of 0.14 kg (0.3 lb) per month of treatment, compared with mean increases of 0.91 kg, 0.23 kg, and 0.18 kg per month (2.0 lb, 0.5 lb, and 0.4 lb per month, respectively) during treatment with olanzapine, quetiapine, and risperidone, respectively, the other SGAs tested (Lieberman *et al.* 2005). A meta-analysis of pooled data from nine placebo-controlled RCTs suggested no significant differences in weight gain between patients treated with ziprasidone and those receiving placebo (Gao *et al.* 2013).

Both short-and long-term studies have shown that ziprasidone has minimal adverse effects on glucose levels, plasma insulin levels, insulin resistance, and fasting and nonfasting lipid levels (Daniel *et al.* 1999; Glick *et al.* 2001; Rettenbacher *et al.* 2006; Simpson *et al.* 2004a, 2005), in contrast to the adverse effects detected with some active comparators. For example, olanzapine treatment can produce statistically significant increases in fasting glucose and insulin levels (Glick *et al.* 2001; Hardy *et al.* 2003; Simpson *et al.* 2002, 2005). In the CATIE phase 1 study, ziprasidone treatment was associated with minimal drug exposure-adjusted mean increases in blood glucose (+ 2.9 +- 3.4 mg/dL) and hemoglobin A1c (+ 0.11 +- 0.09%) and decreases in plasma triglycerides ([?] 16.5+- 12.2 mg/dL) and total cholesterol ([?] 8.2 +- 3.2 mg/dL) (Lieberman 2007). In the CATIE phase 2 study, ziprasidone-treated patients showed minimal drug exposure-adjusted mean increases in blood glucose (+ 0.8 +- 5.6 mg/dL) and hemoglobin A1c (+ 0.46 +- 0.3%) and decreases in triglycerides ([?] 3.5 +- 20.9 mg/dL) and total cholesterol ([?] 10.7 +- 5.1 mg/dL) (Stroup *et al.* 2006).

A number of medications, including psychotropic medications, can increase the duration of the QTc interval (i.e., the QT interval corrected for heart rate). Basic research suggests plausible mechanisms by which an increase in the QTc interval could increase the risk of sudden cardiac death, and clinical investigations suggest that certain small subgroups of the general population may have an increased risk of sudden cardiac death--for example, individuals with a family history of congenital long QT syndrome (> 500 milliseconds) and those who concomitantly use drugs that markedly increase the QTc interval (e.g., by > 60 milliseconds) via either pharmacokinetic or pharmacodynamic interactions (Montanez *et al.* 2004). These potential risks have understandably led to regulatory interest in the effects of drugs on the QTc interval. It should be noted that epidemiological studies in the general population suggest that modest prolongations of the QTc interval are not a risk factor for cardiovascular mortality or sudden death, so any risk in the general population of modest QTc prolongations is likely to be small and difficult to detect reliably (Montanez *et al.* 2004). When considered alongside risks such as obesity, hypercholesterolemia, diabetes, hypertension, physical inactivity, or cigarette smoking, each with well-characterized effects in the general population, modest QTc prolongations do not represent a comparable risk factor for cardiovascular mortality or sudden death in the general population.

Against this background, thioridazine, following decades of use, was required to add to its prescribing information a black box warning related to its effects on prolonging the QTc interval. Other FGAs, including haloperidol, are also associated with some risk of QTc interval prolongation (Gury *et al.* 2000; O'Brien *et al.* 1999). The rate of occurrence of torsades de pointes with FGAs has been estimated as "10-15 such events in 10,000 person-years of observation" (Glassman and Bigger 2001, p. 1774). Ziprasidone, like certain other antipsychotic agents, can induce orthostatic hypotension, in particular early in treatment exposure, which can lead to transient tachycardia, dizziness, or syncope (Swainston Harrison and Scott 2006). However, tachycardia has been observed to be infrequent and to be as common as in patients treated with placebo (Swainston Harrison and Scott 2006). Tachycardia and syncope related to hypotension need to be distinguished from the ventricular arrhythmias that in rare cases can occur in relation to QTc interval prolongation.

Ziprasidone treatment has been demonstrated to result in a modestly increased risk of QTc interval prolongation (Pfizer Inc. 2020). This QTc interval prolongation at C_{max} (mean increase > 15 milliseconds) is 9-14 milliseconds greater than that seen with risperidone, olanzapine, quetiapine, or haloperidol but approximately 14 milliseconds less than that seen with thioridazine. Unlike with thioridazine, the modest effect of ziprasidone on the QTc interval is not worsened by the presence of commonly encountered inhibitors of drug metabolism. In clinical trials of ziprasidone monotherapy that reported QTc interval changes, in studies of high-dosage intramuscular administration, and in case reports of ziprasidone overdose, there was no evidence of any significant clinical sequelae such as torsades de pointes or sudden death (Arato *et al.* 2002; Arbuck 2005; Daniel 2003; Gomez-Criado *et al.* 2005; Harrigan *et al.* 2004; Insa Gomez and Gutierrez Casares 2005; Levy *et al.* 2004; Lieberman 2007; Miceli *et al.* 2004, 2010; Montanez *et al.* 2004; Nemeroff *et al.* 2005; Tan *et al.* 2009; Taylor 2003; Weiden *et al.* 2002, 2003a). These findings are consistent with analyses of large population samples, which have failed to demonstrate any association between QTc interval duration and either cardiovascular or all-cause mortality (Goldberg *et al.* 1991).

Rare cases of torsades de pointes have been reported with a number of different medications, including ziprasidone, but the incidence of these events appears to be below the known prevalence of torsades de pointes in community-based population samples (Heinrich *et al.* 2006). The U.S. prescribing information for ziprasidone suggests that clinicians should nonetheless be cognizant of this potential risk and be aware of circumstances that may increase the risk of torsades de pointes and/or sudden death in association with the use of any drugs that can prolong the QTc interval. Such circumstances include the presence of bradycardia, hypokalemia, or hypomagnesemia; concomitant use of other medications known to cause clinically significant QT prolongation (although an additive effect with ziprasidone has not been established); and the presence of congenital long QT syndrome. The U.S. prescribing information further states that ziprasidone should not be used by patients who have significant cardiovascular conditions, such as uncompensated heart failure or a cardiac arrhythmia, or by those who have had a recent acute myocardial infarction or persistent QTc interval measurements of greater than 500 milliseconds, and the prudent clinician might consider using the same caution when prescribing many other antipsychotic and psychotropic medications currently in use. A comprehensive review of the cardiac safety of antipsychotics (Hasnain and Vieweg 2014) reached a similar conclusion--that little evidence exists that antipsychotic drug-associated QTc interval prolongation is in itself sufficient to cause torsades de pointes in the absence of other risk factors that facilitate or attenuate the progression of drug-associated QTc interval prolongation to torsades de pointes.

Summary for Ziprasidone

Ziprasidone was the fourth atypical antipsychotic following clozapine to become available in the United States. This agent has a unique pharmacological profile, with the highest 5-HT_{2A}/D_2 affinity ratio among currently available agents, potent serotonin and norepinephrine reuptake inhibition activity, agonist activity at 5-HT_{1A} receptors, and clinically relevant antagonist activity at various 5-HT_2 receptor subtypes. Ziprasidone has demonstrated rapid onset and sustained efficacy for the treatment of schizophrenia, schizoaffective disorder, and bipolar mania, with promising evidence of favorable mood, cognitive, and prosocial effects. It is available in an intramuscular formulation for the treatment of acute agitated psychosis and was approved by the European Medicines Agency, but not the FDA, for use in treating bipolar mania in children and adolescents 10-17 years of age.

Ziprasidone has highly favorable safety and tolerability profiles with limited potential for drug-drug and drug-disease interactions--critical issues for a patient population that generally has a high burden of medical comorbidity and is commonly exposed to complex polypharmacy. The adverse-effect profile of ziprasidone is particularly noteworthy in areas that are key to safety and tolerability for patients with major mental disorders such as schizophrenia and bipolar disorder, in that it includes low drug-related risk for acute EPS and minimal effects on cardiometabolic risk factors such as obesity and dyslipidemia.

Asenapine

History and Discovery

Asenapine is available in two relatively novel formulations: as a sublingual tablet and as a transdermal patch. Sublingual asenapine was initially approved by the FDA in August 2009 for the treatment of acute schizophrenia and acute manic or mixed episodes associated with bipolar I disorder in adults. It was subsequently approved for maintenance treatment of schizophrenia in adults, for adjunctive use with lithium or valproate in the treatment of acute manic or mixed episodes associated with bipolar I disorder in adults, and as a monotherapy for bipolar mania in pediatric patients (ages 10-17 years [Allergan USA 2021]). In addition to the original unflavored formulation, a black-cherry-flavored version of sublingual asenapine was approved for the U.S. market in 2010 and is currently available as 2.5-, 5-, and 10-mg tablets.

Asenapine transdermal system (Secuado; manufactured by Hisamitsu Pharmaceutical Co., Inc., and distributed by Noven Therapeutics) was approved by the FDA in October 2019 and is currently available in patch strengths of 3.8, 5.7, and 7.6 mg/24 hours (equivalent to asenapine sublingual tablets 5 mg bid, 7.5 mg bid, and 10 mg bid, respectively). It is the first patch to become available in the United States for the treatment of adults with schizophrenia (Musselman *et al.* 2021). This formulation potentially simplifies the use of this antipsychotic by reducing the dosing frequency from twice daily (recommended for the sublingual tablet) to once daily (recommended for the patch). With the patch there are no food and drink restrictions, and dysgeusia (distorted or bad taste) and hypoesthesia of the tongue are avoided.

Structure-Activity Relations and Pharmacological Profile

Asenapine is a second-generation (atypical) antipsychotic that belongs to the chemical class of dibenzo-oxepino pyrroles (Figure 31-2).

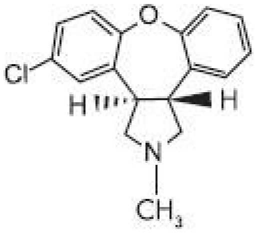

FIGURE 31-2. Chemical structure of asenapine.

Asenapine's receptor binding profile is notable for high affinity (K_i [values in nM]) for several serotonin receptor subtypes, including 5-HT_{2C} (0.03), 5-HT_{2A} (0.06), 5-HT_7

(0.13), 5-HT_{2B} (0.16), and 5-HT_6 (0.25), and for several dopamine receptor subtypes, including D_3 (0.42), D_2 (1.3), D_1 (1.4), and D_4 (1.1) (Allergan USA 2021; Shahid *et al.* 2009). Asenapine has high binding affinities to H_1 (1.0) receptors and to norepinephrine a_1 (1.2) and a_2 (1.2) receptors. It binds with somewhat lower affinity to 5-HT_5 (1.6), 5-HT_{1A} (2.5), and 5-HT_{1B} (4.0) receptors and H_2 (6.2) receptors. It binds very weakly to M_1 (8,128) receptors. Asenapine acts as an antagonist at all of these receptors.

Asenapine has approximately 38 metabolites, none highly prevalent. These metabolites have few clinically relevant effects either because of their lower affinity for the relevant receptors or because of their inability to cross the blood-brain barrier (Citrome 2009a, 2014a; U.S. Food and Drug Administration 2009). Although the precise mechanism of action of asenapine in the treatment of schizophrenia is unknown, it is thought that antagonism at the D_2 and 5-HT_{2A} receptors mediates the drug's antipsychotic activity (Allergan USA 2021). In studies using PET, asenapine demonstrated dose-dependent D_2 receptor occupancy (dose range 0.1-4.8 mg), with a significant correlation between D_2 occupancy and plasma concentration (U.S. Food and Drug Administration 2009). Sublingual administration of 4.8 mg bid results in a mean D_2 occupancy of 79% approximately 3-6 hours after dosing.

Pharmacokinetics and Drug-Drug Interactions

When administered orally, asenapine is absorbed primarily in the oral mucosa. It is formulated as a highly porous, rapidly dissolving tablet for sublingual administration, with a resulting bioavailability of approximately 35% (Schering-Plough Research Institute 2009; U.S. Food and Drug Administration 2009). If the tablet is swallowed rather than allowed to dissolve orally, the drug's bioavailability is reduced to less than 2% because of high hepato-gastrointestinal first-pass metabolism (Allergan USA 2021; U.S. Food and Drug Administration 2009). Patient instructions are to place the tablet under the tongue and to refrain from eating or drinking for 10 minutes after administration, because drinking water sooner than 10 minutes can result in reduced bioavailability of asenapine (Allergan USA 2021).

Although asenapine was developed for sublingual administration, absorption will occur even if the tablet is placed elsewhere in the oral cavity, as was demonstrated in a study of healthy men who received single 5-mg doses of asenapine via sublingual, supralingual, and buccal routes (Gerrits *et al.* 2010). Drug exposure with buccal administration (i.e., cheeking) as measured by plasma levels was almost 25% higher than that with sublingual administration, whereas exposure with supralingual administration was 6% lower. However, these differences in exposure by oral administration site are small in relation to the wide variability in asenapine's pharmacokinetics observed across the clinical studies used to obtain regulatory approval, in which overall exposure varied by 37%, with a mean interindividual variability of 26% and a mean intraindividual variability of 26% (U.S. Food and Drug Administration 2009). Doubling the sublingually administered dosage from 5 mg to 10 mg bid results in less than linear (1.7 times) increases in both the amount of exposure and the maximal concentration (Allergan USA 2021).

Peak plasma levels are reached 30-90 minutes after sublingual administration, and asenapine has a mean terminal half-life of approximately 24 hours (Allergan USA 2021; Schering-Plough Research Institute 2009; U.S. Food and Drug Administration 2009). Clinical trials supporting the approval of sublingual asenapine were conducted using twice-daily dosing, which resulted in the recommendation for twice-daily dosing in the product labeling. However, barring tolerability issues when starting treatment with asenapine, once-daily dosing in the evening may be feasible given the half-life.

The pharmacokinetic profile of the transdermal asenapine system demonstrates dose-proportional kinetics and sustained delivery of asenapine with a low peak-to-trough plasma level ratio (Suzuki *et al.* 2021). Asenapine transdermal system is available in three patch sizes--20 cm^2 (3.8 mg/24 hours), 30 cm^2 (5.7 mg/24 hours), and 40 cm^2 (7.6 mg/24 hours)--

that deliver the equivalent of sublingual asenapine 5 mg bid, 7.5 mg bid, and 10 mg bid (Noven Therapeutics 2022).

Asenapine is metabolized in the liver primarily through direct glucuronidation by UGT1A4 and oxidative metabolism by CYP isoenzymes (predominantly CYP1A2). Asenapine has a large volume of distribution and is highly bound (95%) to plasma proteins, including albumin and a_1-acid glycoprotein. Despite the fact that smoking can induce CYP1A2, concomitant smoking had no substantial effect on the pharmacokinetics of asenapine when tested in healthy male subjects (U.S. Food and Drug Administration 2009). Fluvoxamine, a potent CYP1A2 inhibitor, can increase exposure to asenapine by 29% and therefore should be coadministered with caution (Allergan USA 2021).

Use of asenapine is not recommended in patients with severe hepatic impairment (Child-Pugh class C). Asenapine exposure is on average seven times higher in patients with severe impairment than in those with normal hepatic function. However, no dosage adjustment is required in patients with mild (Child-Pugh class A) or moderate (Child-Pugh class B) hepatic impairment. No dosage adjustment is required for patients with renal impairment.

Asenapine can inhibit CYP2D6, resulting, for example, in twofold increases in paroxetine concentrations (U.S. Food and Drug Administration 2009). The product label advises caution when coadministering asenapine with drugs that are both substrates and inhibitors of CYP2D6 (Allergan USA 2021).

Indications and Efficacy

Sublingual asenapine's efficacy in treating acute schizophrenia in adults was tested in four pivotal short-term randomized, double-blind, placebo-and active comparator-controlled multicenter studies (Citrome 2011b, 2014b). Two studies were accepted by the FDA as supportive of asenapine's efficacy in the acute treatment of schizophrenia in adults (Kane *et al.* 2010; Potkin *et al.* 2007). The efficacy of transdermal asenapine in treating acute schizophrenia was established in a 6-week Phase III randomized, placebo-controlled inpatient study in which asenapine transdermal system (3.8 mg/

24 hours and 7.6 mg/24 hours) demonstrated significant improvement versus placebo at week 6 for the primary endpoint (PANSS total score) and key secondary endpoints (Citrome *et al.* 2020). Transdermal asenapine has neither been tested in, nor approved for, any indication other than schizophrenia.

Sublingual asenapine's efficacy in the treatment of manic or mixed episodes of bipolar I disorder in adults was supported in both of two completed Phase III randomized, placebo-and active comparator-controlled 3-week trials (McIntyre *et al.* 2009a, 2010a). Approximately 1 year after the initial approval of asenapine for these indications, the FDA approved asenapine for the maintenance treatment of schizophrenia (on the basis of a double-blind, placebo-controlled multicenter clinical trial [Kane *et al.* 2011]) and for use as adjunctive therapy with either lithium or valproate in the acute treatment of manic or mixed episodes associated with bipolar I disorder (again on the basis of a placebo-controlled trial [Szegedi *et al.* 2012]). Approval of asenapine for the treatment of bipolar mania in pediatric patients (ages 10-17 years) was obtained in 2015 on the basis of a placebo-controlled trial (Findling *et al.* 2015b).

In adults, the recommended dosage of sublingual asenapine for acute schizophrenia is 5 mg bid; that for bipolar manic or mixed episodes is 10 mg bid (5 mg bid if the drug is administered with lithium or valproate) on the basis of the clinical trials used to obtain regulatory approval. Titration to these target dosages is not necessary. In a modeling and simulation study (Friberg *et al.* 2009), asenapine dosages of 5 and 10 mg bid had similar efficacy in the acute treatment of schizophrenia. In the maintenance study in schizophrenia on which asenapine's approval for that indication was based, the most commonly used dosage was 10 mg bid (Kane *et al.* 2011).

In pediatric patients (ages 10-17 years) with bipolar mania, the recommended starting dosage of sublingual asenapine as monotherapy is 2.5 mg bid, with increases up to 10 mg bid possible.

According to the product label for transdermal asenapine, the initial recommended dosage is 3.8 mg/24 hours (Noven Therapeutics 2022). The dosage may be increased to 5.7 mg/24 hours or 7.6 mg/24 hours, as needed, after 1 week.

Schizophrenia (Sublingual Asenapine)

In one of the two positive trials, 458 patients with acute schizophrenia were randomly assigned to fixed-dosage treatment with asenapine 5 mg bid, asenapine 10 mg bid, placebo, or an active control for assay sensitivity (haloperidol 4 mg bid) for 6 weeks (Kane *et al.* 2010). The primary efficacy endpoint was change from baseline in the PANSS total score (Kay *et al.* 1987). In analyses of the change in the PANSS total score, asenapine 5 mg bid and haloperidol were both superior to placebo, with statistically significant differences seen from day 21 onward. However, asenapine 10 mg bid did not demonstrate an advantage over placebo, a finding that the authors suggested may have been due in part to the high placebo response rate in this trial. Rates of response--defined as a minimum reduction of 30% in the PANSS total score or a CGI-I score of 1 (very much improved) or 2 (much improved)--were 55% for asenapine 5 mg bid, 49% for asenapine 10 mg bid, 43% for haloperidol, and 33% for placebo, yielding numbers needed to treat (NNTs; Citrome 2008) versus placebo of 5 for asenapine 5 mg bid, 7 for asenapine 10 mg bid, and 10 for haloperidol (Citrome 2011b).

In the other short-term acute schizophrenia trial that was considered positive and supportive of asenapine's efficacy, 182 patients were randomly assigned to asenapine 5 mg bid, placebo, or an active control for assay sensitivity (risperidone 3 mg bid) for 6 weeks (Potkin *et al.* 2007). The primary efficacy endpoint was change from baseline in the PANSS total score. Compared with placebo, asenapine produced significantly greater decreases in the PANSS total score from week 2 onward. Risperidone did not statistically significantly separate from placebo. Using the criterion of reduction in the PANSS total score of at least 30%, the researchers categorized 38% of the patients in the asenapine group as responders, compared with 39% of those in the risperidone group and 25% of those in the placebo group, yielding NNTs versus placebo of 8 for asenapine and 7 for risperidone (Citrome 2011b).

Two other 6-week acute schizophrenia trials were conducted (Citrome 2011b; U.S. Food and Drug Administration 2009). One trial was considered negative because asenapine 5 mg bid or 10 mg bid failed to separate from placebo, whereas the active control (olanzapine 15 mg/day) did separate from placebo. The other trial was considered a failed trial because neither asenapine 5 mg bid or 10 mg bid nor the active control (olanzapine 10-20 mg/day) separated from placebo. An additional double-blind trial was conducted in which 532 adult Asian participants from Japan, Korea, and Taiwan were randomly assigned to receive asenapine 5 mg bid, asenapine 10 mg bid, or placebo for 6 weeks (Kinoshita *et al.* 2016). The primary efficacy endpoint was change from baseline in the PANSS total score. Improvements from baseline in the PANSS total score were significantly greater among the patients receiving asenapine 5 mg bid or 10 mg bid, compared with those receiving placebo, from days 14 and 7, respectively. Using the criterion of reduction in the PANSS total score of at least 30%, the researchers categorized 39% of the patients in the asenapine 5-mg bid group and 44% of those in the 10-mg bid group as responders, compared with 21% of those in the placebo group, yielding NNTs versus placebo of 6 for asenapine 5-mg bid and 5 for asenapine 10-mg bid. An 8-week placebo-controlled, double-blind trial in 306 adolescent (ages 12-17 years) patients with schizophrenia failed to demonstrate asenapine's efficacy at dosages of 2.5 mg bid and 5 mg bid (Findling *et al.* 2015a).

Asenapine's longer-term efficacy in treating schizophrenia was examined in a published 1-year double-blind study in 1,225 individuals with schizophrenia or schizoaffective disorder. Patients were randomly assigned to receive asenapine (5 mg bid for the first week and then flexible dosing of 5 mg bid or 10 mg bid) or olanzapine (10 mg/day for the first week and then flexible dosing of 10 mg/day or 20 mg/day) (Schoemaker *et al.* 2010). The study had no placebo arm. Rates of discontinuation because of insufficient therapeutic effect were 25.1% for asenapine and 14.5% for olanzapine (NNT = 10 for olanzapine vs. asenapine to avoid discontinuation because of insufficient therapeutic effect). Changes from baseline in the PANSS total score were similar for asenapine and olanzapine at week 6 but showed a statistically significant difference in favor of olanzapine at endpoint (last observation carried forward analysis). Among the patients who completed the entire year-long trial (i.e., observed cases), changes in the PANSS total score were similar for asenapine and olanzapine at week 6 and at week 52. Completers were eligible to participate in an extension study in which clinical stability was further demonstrated (Schoemaker *et al.* 2012).

Asenapine's efficacy in the maintenance phase of schizophrenia was demonstrated in a published 26-week double-blind, placebo-controlled multicenter clinical trial (Kane *et al.* 2011). Patients were randomly assigned either to continue receiving asenapine or to receive placebo after establishing stability on asenapine during the 26 weeks of open-label treatment immediately prior. Of the 700 enrolled patients who were treated with open-label asenapine, 386 had symptoms that met stability criteria and entered the double-blind phase. Times to relapse/impending relapse and to discontinuation for any reason were significantly longer with asenapine than with placebo. The incidence of relapse or impending relapse was 12.1% for asenapine and 47.4% for placebo (NNT = 3). Completion rates were 69.6% for asenapine and 37.5% for placebo (NNT = 4). The most commonly used dosage of asenapine was 10 mg bid in both the open-label and the double-blind phase.

In two randomized, double-blind 26-week studies and their respective 26-week extensions, Buchanan *et al.* (2012) tested the hypothesis that asenapine is superior to olanzapine for treating persistent negative symptoms of schizophrenia and assessed the comparative long-term efficacy and safety of the two agents. Approximately 1,000 subjects participated. In the two core studies, 26-week completion rates were 64.7% and 49.6% with asenapine versus 80.4% and 63.8%, respectively, with olanzapine. In the two extension studies, completion rates were 84.3% and 66.3% with asenapine versus 89.0% and 80.9%, respectively, with olanzapine. Asenapine was not superior to olanzapine in producing change in the 16-item Negative Symptom Assessment total score in either core study, but it was superior to olanzapine at week 52 in one of the extension studies. Weight gain was consistently lower with asenapine. The incidence of EPS-related adverse events was higher with asenapine, but change in the

Extrapyramidal Symptom Rating Scale--Abbreviated total score did not differ significantly between treatments.

Schizophrenia (Transdermal Asenapine)

The efficacy of transdermal asenapine in treating acute schizophrenia was evidenced in a 6-week Phase III randomized, placebo-controlled study in which 614 inpatients were randomly assigned to receive transdermal asenapine 3.8 mg/24 hours (*n* = 204), transdermal asenapine 7.6 mg/24 hours (*n* = 204), or placebo (*n* = 206) (Citrome *et al.* 2020). Both asenapine dosages demonstrated statistically significant improvement versus placebo at week 6 for the primary endpoint (PANSS total score) and key secondary endpoints, with a greater magnitude of effect for the lower dosage. The lower dosage began to separate from placebo on the PANSS and CGI-S at week 2, and the higher dosage began to separate on the PANSS at week 3 and on the CGI-S at week 2. Rates of PANSS response (defined as a minimum reduction of 30% in the PANSS total score) were 30.8% for asenapine 3.8 mg/24 hours, 29.6% for asenapine 7.6 mg/24 hours, and 18.7% for placebo, yielding NNTs versus placebo of 9 and 10 for the lower dosage and higher dosage, respectively.

Rates of CGI-I response (defined as a score of 1 [very much improved] or 2 [much improved]) were 49.8% for asenapine 3.8 mg/24 hours, 43.3% for asenapine 7.6 mg/24 hours, and 34.0% for placebo, yielding NNTs versus placebo of 7 and 11 for the lower dosage and higher dosage, respectively.

A post hoc analysis on symptoms of hostility suggested that transdermal asenapine has a specific antihostility effect, a finding that was independent of sedation (Citrome *et al.* 2022).

Bipolar Disorder (Sublingual Asenapine)

In two identically designed 3-week acute studies of asenapine in the treatment of bipolar manic or mixed episodes (McIntyre *et al.* 2009a, 2010a), 977 subjects were randomly assigned to receive flexibly dosed asenapine 5-10 mg bid (starting dosage 10 mg bid), olanzapine 5-20 mg/day (starting dosage 15 mg/day), or placebo. The primary outcome measure for each of these studies was change from baseline in the Young Mania Rating Scale (YMRS; Young *et al.* 1978) total score. In the first study (McIntyre *et al.* 2009a), the YMRS total score was statistically significantly more improved from baseline to day 21 for asenapine and olanzapine compared with placebo. Sustained statistically significant improvement in the YMRS score compared with placebo was noted for asenapine and olanzapine from day 2 onward. Percentages of subjects whose symptoms met criteria for response (defined as a [?] 50% decrease from baseline in the YMRS total score) and remission (YMRS total score [?] 12) were higher with asenapine (42.3% and 40.2%, respectively) than with placebo (25.2% and 22.3%, respectively), yielding NNTs for response and for remission versus placebo of 6. The NNT for response for olanzapine versus placebo was 5, and that for remission was 6.

In the second study (McIntyre *et al.* 2010a), the YMRS total score also was statistically significantly improved from baseline to day 21 with asenapine and olanzapine compared with placebo, with sustained statistically significantly greater improvement in the YMRS total score versus placebo noted for asenapine and olanzapine from day 2 onward. In post hoc analyses, change in the YMRS total score from baseline to day 21 was significantly greater for olanzapine than for asenapine with last observation carried forward analysis but not with mixed models for repeated measures analysis. Rates of response (42.6%) and remission (35.5%) with asenapine did not differ significantly from those with placebo (34% and 30.9%, respectively), yielding NNTs of 12 and 22, respectively. Olanzapine was superior to placebo in rates of response (54.7%) and remission (46.3%), with NNTs for olanzapine versus placebo of 5 and 7, respectively, and NNTs for olanzapine versus asenapine of 9 and 10, respectively. On the basis of these studies, the recommended starting dosage of asenapine monotherapy for acute bipolar mania or mixed episodes in adults is 10 mg bid. However, additional information is available from a 3-week double-blind, placebo-controlled, fixed-dosage study of asenapine 5 mg bid and 10 mg bid in adults with an acute bipolar I disorder manic or mixed episode (Landbloom *et al.* 2016). Both asenapine dosages were statistically superior to placebo in mean change from baseline to day 21 in the YMRS total score, which suggests that 5 mg bid can be an adequate dosage for adults with acute bipolar mania or mixed episodes. However, in this trial, neither asenapine dosage had significantly more YMRS responders or remitters at day 21 than placebo.

Asenapine's longer-term efficacy in patients with manic or mixed episodes of bipolar disorder was assessed in a 9-week extension (McIntyre *et al.* 2009b) of the original two pivotal studies (McIntyre *et al.* 2009a, 2010a), followed by an additional 40-week extension (McIntyre *et al.* 2010b). A total of 504 participants received at least one dose of double-blind trial medication during the 9-week extension trial. These patients included 181 subjects who had been treated with asenapine and 229 who had been treated with olanzapine in the feeder trials (and who continued on the same treatment in the extension). In addition, 94 subjects who had been treated with placebo in the feeder trials were blindly allocated to receive asenapine 5-10 mg bid in the extension trial. The primary efficacy analysis demonstrated that asenapine was statistically not inferior to olanzapine as measured by change in the YMRS total score from baseline to day 84 for the observed case subjects who had 3 weeks of previous exposure to the study medication. The proportions of participants who were YMRS responders and remitters were similar in the asenapine and olanzapine groups: the rates of response at last observation carried forward endpoint were 77% and 82% with asenapine and olanzapine, respectively, and the rates of remission were 75% and 79%, respectively. Among 218 patients who were subsequently enrolled for another 40 weeks of double-blind treatment, maintenance of efficacy was observed with both asenapine and olanzapine, with no differences in response or remission rates between the two agents.

Another study tested the efficacy of asenapine 5 mg bid in the treatment of an acute manic or mixed episode when combined with lithium or divalproex over 12 weeks (Szegedi *et al.* 2012), and its findings supported this indication as approved by the FDA (Allergan USA 2021). Adjunctive asenapine produced significantly more improvement in mania than did placebo at week 3 (primary endpoint) and weeks 2-12. The YMRS response rates were similar at week 3 but significantly better with asenapine at week

12. The YMRS remission rates and changes from baseline on the CGI-Bipolar (CGI-BP) scale for mania and overall illness were significantly better with asenapine at weeks 3 and 12. Patients who completed the core study were eligible for a 40-week double-blind extension assessing safety and tolerability (Szegedi *et al.* 2012).

Asenapine's efficacy in the treatment of acute mania in pediatric patients (ages 10-17 years) was established in a single 3-week placebo-controlled, double-blind trial of 403 patients, of whom 302 received asenapine at fixed dosages of 2.5 mg bid, 5 mg bid, and 10 mg bid (Findling *et al.* 2015b). All patients were started on 2.5 mg bid, and dosages were titrated upward every 3 days in a stepwise fashion for patients randomly assigned to receive the higher dosages. Asenapine was statistically superior to placebo in improving the YMRS total and CGI-BP severity of illness scores. YMRS responder rates were 42%, 54%, and 52% for asenapine 2.5 mg bid, 5 mg bid, and 10 mg bid, respectively, versus 28% for placebo, yielding corresponding NNT values for asenapine versus placebo of 8, 4, and 5.

Agitation (Sublingual Asenapine)

Although asenapine is not specifically approved for this indication, it was tested for the management of agitation in an RCT (Pratts *et al.* 2014). Adults ages 18-65 years (*N* = 120, any diagnosis) manifesting agitation in an emergency department and found to have a score of [?] 14 on the PANSS-Excited Component (PANSS-EC) were randomly assigned to receive either a single sublingual 10-mg tablet of asenapine or matching placebo. Change in the PANSS-EC score at 2 hours was statistically significantly greater for the asenapine-treated subjects compared with the placebo-treated subjects, with an effect noted at 15 minutes, the earliest time point at which outcome was measured. The NNT value for response to asenapine versus placebo was 3, an effect size comparable to that observed in prior studies of intramuscular antipsychotics. This study awaits replication.

Side Effects and Toxicology

Common adverse reactions to sublingual asenapine observed in short-term trials (incidence [?] 5% and twofold greater than placebo) were akathisia, oral hypoesthesia (numbness), and somnolence in adult patients with schizophrenia; somnolence, dizziness, EPS other than akathisia, and increased weight for monotherapy in adult patients with bipolar manic or mixed episodes; and somnolence and oral hypoesthesia for adjunctive therapy in adult patients with bipolar manic or mixed episodes (Allergan USA 2021). Among the pediatric patients with bipolar disorder, common adverse reactions observed with sublingual asenapine as monotherapy were somnolence, dizziness, dysgeusia, oral paresthesias, nausea, increased appetite, fatigue, and increased weight (Allergan USA 2021).

Somnolence is the single most common adverse event associated with sublingual asenapine treatment, similar to all approved antipsychotic medications, although the magnitude of the effect varies by class. The product label describes this effect as usually transient, with the highest incidence reported during the first week of treatment (Allergan USA 2021). The highest rates of somnolence in adults were observed in the short-term acute manic/mixed-episode bipolar trials (most common dosage 10 mg bid), in which somnolence was reported in 24% of patients receiving asenapine versus 6% of patients receiving placebo, for a number needed to harm (NNH) of 6; rates of reported somnolence in the short-term schizophrenia trials (dosage 5 mg bid or 10 mg bid) were 13% for asenapine versus 7% for placebo, yielding an NNH of 17 (Citrome 2009a). Comparisons of other antipsychotics against placebo on the outcome of somnolence in short-term acute trials of schizophrenia yielded a broad range of incidence rates, resulting in NNH values that ranged from 7 for olanzapine or quetiapine extended release to a not statistically significant 42 for paliperidone (Citrome and Nasrallah 2012). Although somnolence was frequently reported, somnolence/sedation led to discontinuation in only a small proportion (0.6%) of adult patients treated with sublingual asenapine (Allergan USA 2021).

Dizziness can also occur and is attributable to asenapine's a_1-adrenergic antagonist activity; however, rates of syncope were observed to be low among patients, in contrast to rates observed among healthy volunteers in the clinical pharmacology trials (U.S. Food and Drug Administration 2009). Asenapine has a dose-related association with EPS and akathisia, although the frequency of these events is substantially lower with asenapine than with haloperidol (Citrome 2009a).

Unique to asenapine is the possibility of oral hypoesthesia, spontaneously reported as an adverse reaction in about 5% of the participants with acute schizophrenia in the clinical trials of the sublingual formulation (Allergan USA 2021). Directly asking patients about oral hypoesthesia may yield higher rates of this adverse effect, as was observed in a study that examined the effect of absorption site on the pharmacokinetics of asenapine in healthy male subjects (Gerrits *et al.* 2010). In this study, reported rates of oral paresthesias were 75.8%, 55.9%, and 45.7% for the sublingual, supralingual, and buccal absorption sites, respectively.

Asenapine has a mild effect on the QTc interval similar to that seen with quetiapine (Chapel *et al.* 2009, 2011). Hypersensitivity reactions have been reported with asenapine, in some cases occurring after the first dose, and this risk is now highlighted in the product labeling (Allergan USA 2021). Asenapine's effects on prolactin levels in the short-term schizophrenia and bipolar manic/mixed-episode studies in adults revealed no clinically relevant changes.

In the 6-week acute schizophrenia trials of sublingual asenapine, clinically relevant weight gain ([?] 7% over baseline body weight) was observed in 4.9% of subjects receiving asenapine versus 2% of those receiving placebo. In the 3-week acute bipolar manic/mixed-episode studies, clinically relevant weight gain was observed in 5.8% of subjects receiving asenapine versus 0.5% of those receiving placebo. In addition to a favorable weight gain profile, asenapine has shown minimal effects on glucose-related laboratory variables such as fasting glucose and fasting insulin (Schering-Plough Research Institute 2009).

Of interest are longer-term safety and tolerability comparisons of sublingual asenapine with other antipsychotics. In a 1-year double-blind RCT comparing asenapine with olanzapine (Schoemaker *et al.* 2010), the incidence of treatment-emergent adverse events was 82% in both groups. Mean weight gain was 0.9 kg with asenapine and 4.2 kg with olanzapine. The proportion of patients experiencing clinically relevant weight gain ([?] 7% over baseline) was approximately 35% for olanzapine and approximately 15% for asenapine (NNH = 5 for olanzapine vs. asenapine). No notable changes or between-group differences were seen in measures of total cholesterol or glucose, but triglyceride levels rose substantially with olanzapine and declined slightly with asenapine. In the 2-year blinded extension study (Schoemaker *et al.* 2012), mean body weight during the extension did not change beyond the weight gain in the core study. In the core study, EPS reported as adverse events were more common with asenapine (18%) than with olanzapine (8%) (NNH = 10 for asenapine vs. olanzapine). The most commonly reported type of movement disorder in the asenapine and olanzapine groups was akathisia, with treatment-emergent rates of 10% for asenapine and 4% for olanzapine (NNH = 17 for asenapine vs. olanzapine). In the 2-year blinded extension study, incidence rates of EPS-related adverse events that started during the extension were lower for both asenapine (4.5%) and olanzapine (3.3%) compared with those that started during the core study. Not many new cases of akathisia were reported during the extension period. There was little change in EPS severity during the extension of treatment.

Safety and tolerability outcomes are available from a 40-week extension of the acute bipolar trials (McIntyre *et al.* 2010b), in which clinically relevant weight gain occurred in 21.9%, 39.2%, and 55.1% of patients in the placebo/asenapine, asenapine, and olanzapine groups, respectively. The NNH for clinically relevant weight gain for olanzapine versus asenapine was 7. The percentage of patients shifting to above a prespecified akathisia global rating scale threshold was higher in the asenapine group compared with the placebo/asenapine and olanzapine groups.

Tolerability of asenapine in pediatric patients (ages 10-17 years) in the 3-week bipolar mania trial differed from that in the adult trials in terms of higher reported rates of somnolence, oral paresthesias (oral hypoesthesia, oral paresthesia, and oral dysesthesia), and weight gain (Allergan USA

2021). Rates of somnolence were 49% for asenapine (all dosages) versus 12% for placebo, yielding an NNH of 3, with no clear dose-response relationship. Rates of fatigue were substantially lower (9% and 5% for asenapine and placebo, respectively), but with a dose-response effect and a rate of 14% for subjects receiving asenapine 10 mg bid. Rates of oral paresthesias were 27% for asenapine (all dosages) versus 4% for placebo, yielding an NNH of 5. The proportions of patients experiencing clinically relevant weight gain ([?] 7% over baseline body weight) were 12%, 8.9%, and 8% for asenapine 2.5 mg bid, 5 mg bid, and 10 mg bid, respectively, versus 1.1% for placebo, yielding corresponding NNH values of 10, 13, and 15. A 50-week open-label, flexible-dose extension trial was available for those who completed the 3-week acute trial (Findling *et al.* 2016). Among the tolerability variables of interest, combined somnolence/sedation/hypersomnia occurred most frequently (42.4%). In total, 34.8% of the participants experienced clinically significant weight gain.

The systemic safety profile of transdermal asenapine in patients with schizophrenia was consistent with that of sublingual asenapine, absent the dysgeusia and hypoesthesia of the tongue observed with sublingual asenapine. The incidence of adverse reactions at the application site was higher for asenapine transdermal system (14.2%, 7.6 mg/24 hours; 15.2%, 3.8 mg/24 hours) than for placebo (4.4%). However, discontinuations due to application site reactions or skin disorders (urticaria, pruritus) were infrequent ([?] 0.5% per treatment group).

Summary for Asenapine

Asenapine's efficacy is evidenced both in short-term acute clinical trials and in longer-term studies. In the mind of the clinician, asenapine will likely be measured against other "metabolically friendly" SGAs such as ziprasidone, aripiprazole, iloperidone, lurasidone, brexpiprazole, and cariprazine, as well as newer agents in the antipsychotic development pipeline (Citrome 2011a, 2013, 2015). Differences among these choices include dosing factors (daily vs. twice-daily dosing, the need for dosage titration, special requirements for administration with or without food) as well as specific side-effect profiles.

The sublingual formulation of asenapine is unique in being the only antipsychotic that is absorbed primarily in the oral mucosa. Nonadherence by cheeking is minimized. The possibility of oral hypoesthesia and dysgeusia, a medication effect likely not experienced previously by the patient, necessitates advance warning. Asenapine transdermal system is the first patch available in the United States for the treatment of adults with schizophrenia. This formulation simplifies adherence by reducing the dosing frequency from twice daily (recommended for the sublingual tablet) to once daily (recommended for the patch) and avoids food and drink restrictions as well as dysgeusia and hypoesthesia of the tongue.

In summary, asenapine's place in the treatment of schizophrenia and bipolar manic or mixed episodes is likely to be in patients for whom metabolic concerns are of import and in patients who would prefer a sublingual or transdermal preparation. Substantial heterogeneity exists among the different antipsychotics and among individual patients (Volavka and Citrome 2009), so asenapine has a relevant place on a formulary. Cost may be an impediment to the use of asenapine, given the availability of inexpensive generic versions of risperidone, quetiapine, ziprasidone, and olanzapine in the United States as well as other generic SGAs in other countries.

CHAPTER 32

Iloperidone

Peter F. Buckley, M.D.

Adriana E. Foster, M.D.

History and Discovery

Approved by the FDA in 2009 for the treatment of schizophrenia, iloperidone meets the now generally appreciated profile of second-generation antipsychotics (SGAs) in that it has a complex pharmacology (with a predilection for dopamine and serotonin antagonism) and little propensity for extrapyramidal side effects (EPS), as well as efficacy against key symptoms of schizophrenia, as shown in placebo-controlled clinical trials (Rado and Janicak 2010; Weiden 2012). Iloperidone's efficacy has been demonstrated at a dosage range of 12-24 mg/day, with no clear advantage evident at higher dosages. To minimize the risk of dizziness and postural hypotension consequent to iloperidone's antagonism of a_1-adrenergic receptors, it is recommended that the medication be initiated at 1 mg orally twice daily and titrated upward with caution. Increases to reach the target dosage should not exceed 2 mg twice daily (e.g., 4 mg/day). Control of symptoms may be delayed during the first 1-2 weeks of treatment compared with other SGAs that do not require titration (Vanda Pharmaceuticals 2016). Clinical experience with iloperidone is accruing, as is comparative information on iloperidone in relation to other SGAs (Potkin *et al.* 2013; Rado and Janicak 2014; Tarazi and Stahl 2012). Additional clinical trials of iloperidone are ongoing (see www.clinicaltrials.gov).

Structure-Activity Relations and Pharmacological Profile

Iloperidone is an SGA of the piperidinyl-benzisoxazole class (Figure 32-1). Structurally similar benzisoxazole derivatives include risperidone and its metabolite paliperidone as well as ziprasidone. Iloperidone's chemistry and specific binding profile across multiple neuroreceptors are complex (Citrome 2010; Kalkman *et al.* 2003). In brief, similar to several other SGAs, iloperidone is a serotonin$_{2A}$ (5-HT$_{2A}$) and dopamine$_2$ (D$_2$) receptor antagonist. It has strong affinity for dopamine$_3$ (D$_3$) receptors and a lesser (but still more pronounced compared with other SGAs) affinity for dopamine$_4$ (D$_4$) receptors. It also has affinity for both serotonin$_6$ and serotonin$_7$ receptors. Iloperidone is further distinguished by its antagonism of a$_1$-adrenergic receptors. The strength of iloperidone's a$_1$-receptor affinity exceeds that of all other SGAs except clozapine. In contrast, iloperidone has low affinity for serotonin$_{1A}$ (5-HT$_{1A}$) and histamine$_1$ (H$_1$) receptors. Collectively, this constellation of receptor affinities may account for iloperidone's adverse effects of postural hypotension risk, prolactin-elevating capacity, modest propensity for weight gain, and mild sedative effects.

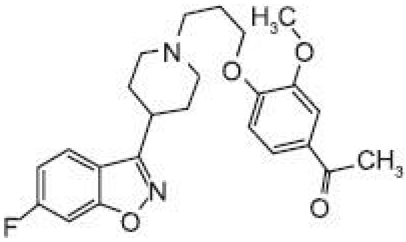

FIGURE 32-1. Chemical structure of iloperidone.

Pharmacokinetics and Disposition

Iloperidone is readily absorbed from the gastrointestinal tract and reaches peak plasma concentrations approximately 2 hours after ingestion. Its absorption is slowed by food, but its bioavailability is unaffected; thus, it can be given either with or without food.

Iloperidone is extensively metabolized by the cytochrome P450 (CYP) enzyme system, in particular the 3A4 and 2D6 isoenzymes. Iloperidone's average half-life in "regular" (extensive) CYP2D6 metabolizers is approximately 24 hours. Clinicians need to be cautious when prescribing iloperidone concurrently with agents that inhibit CYP2D6 and CYP3A4 enzymes, a category that includes several antidepressant medications. Iloperidone dosages should be reduced by one-half when administered in combination with a strong CYP3A4 inhibitor (e.g., ketoconazole, clarithromycin). Similarly, when administered with a strong CYP2D6 inhibitor (e.g., fluoxetine, paroxetine), iloperidone dosages should also be reduced (Vanda Pharmaceuticals 2016). It has been shown that a statistically significantly greater proportion of iloperidone responders than nonresponders have average plasma concentrations of [?] 5 ng/mL. That said, data on blood levels of iloperidone are not available for use in clinical practice (Weiden 2012). In studies performed in vitro, iloperidone at therapeutic concentrations decreased gene expression and protein activity of CYP3A4, a finding that supports potential clinically significant drug interactions between iloperidone and antidepressants, benzodiazepines, macrolide antibiotics, and other medications metabolized by CYP3A4 (Danek *et al.* 2020a, 2020b). Also, dosages should be reduced by one-half in individuals who are CYP2D6 poor metabolizers, which can be determined using available laboratory tests.

Iloperidone is currently available only in tablet form, with multiple tablet strengths to facilitate dosage titration (1, 2, 4, 6, 8, 10, and 12-mg tablets). No liquid or short-term intramuscular or long-acting injectable formulations of this agent have been developed.

There is currently no clinical evidence that the dosage of iloperidone requires adjustment on the basis of age or gender, although it is noteworthy that the potential for postural hypotension may be markedly higher in the elderly. Clinical studies of iloperidone in schizophrenia did not include sufficient numbers of patients age 65 years or older to determine whether older persons respond differently from younger adults. Among more than 3,000 patients treated with iloperidone in the early registration trials, only 25 patients (0.5%) were age 65 years or older, and there were no patients age 75 years or older. Iloperidone's safety and effectiveness in pediatric patients have not yet been well studied; therefore, the drug should not be prescribed to children or adolescents. In addition, iloperidone's teratogenic risk is unknown. It is therefore advised that lactating women who are being treated with iloperidone refrain from breastfeeding their newborns. The most recent FDA recommendations regarding the use of antipsychotics during pregnancy and the neonatal period also apply to iloperidone (see the FDA's MedWatch program at www.fda.gov/Safety/MedWatch); these guidelines note that third-trimester use of iloperidone may cause extrapyramidal and/or withdrawal symptoms in neonates.

Indications and Efficacy

Iloperidone is FDA approved for the acute treatment of schizophrenia. No other indications for iloperidone were under consideration by the FDA at the time of this writing. However, the clinical trials program for this drug now includes investigative studies of mood disorders that are currently ongoing (see www.clinicaltrials.gov).

Schizophrenia

Pivotal Clinical Trials

Iloperidone's FDA approval for the treatment of schizophrenia was predominantly based on four short-term placebo-controlled trials, highlighted in Table 32-1. In addition, two long-term trials have been published (Cutler *et al.* 2013; Kane *et al.* 2008). These studies are described in the following paragraphs. A more complete review of drug development and initial trials in humans is provided elsewhere (Citrome 2010; Rado and Janicak 2014).

TABLE 32-1. Pivotal clinical trials of iloperidone efficacy in patients with schizophrenia or schizoaffective disorder

* Relapse = [?] 25% increase in PANSS-T scores; discontinuation due to lack of efficacy, hospitalization, or CGI increase of 2 points.

Potkin *et al.* (2008) reviewed the 6-week double-blind period of the pivotal trials that evaluated iloperidone's efficacy in the treatment of schizophrenia. All of these trials included screening, an acute double-blind phase, and a long-term maintenance phase.

Study 1 enrolled patients ages 18-65 years with acute or subacute exacerbations of schizophrenia or schizoaffective disorder and with Positive and Negative Syndrome Scale (PANSS) scores [?] 60. A total of 121 patients were randomly assigned to receive iloperidone 4 mg/day, 125 to iloperidone 8 mg/day, 124 to iloperidone 24 mg/day, 124 to haloperidol 15 mg/day, and 127 to placebo. After a screening and a 3-day placebo run-in period as well as a 7-day fixed-titration period, patients received study medication for 5 weeks. The primary objective was to determine the efficacy of iloperidone versus placebo. The primary efficacy variable was change in the PANSS total score (PANSS-T) from baseline to endpoint (day 42 or last visit before discontinuation). Although PANSS-T scores improved significantly from baseline for the iloperidone 12 mg/day ($P = 0.047$) and the haloperidol ($P < 0.001$) groups, improvement for the combined iloperidone 8 mg/day and 12 mg/day group was not significantly different from that for the placebo group. The all-cause discontinuation rates were 57%, 64%, and 58% for iloperidone 4 mg/day, 8 mg/day, and 12 mg/day, respectively; 65% for haloperidol; and 69% for placebo (Potkin *et al.* 2008).

In Study 2, patients selected according to the same inclusion criteria used in Study 1 were randomly assigned to receive iloperidone 4-8 mg/day ($n = 53$; 52% discontinued the study before endpoint) or 10-16 mg/day ($n = 154$; 44% discontinued), risperidone 4-8 mg/day ($n = 153$; 42% discontinued), or placebo ($n = 156$; 60% discontinued). The primary objective was again to determine the efficacy of iloperidone versus placebo. Both dosage ranges of iloperidone resulted in significantly greater symptom improvement (as measured by Brief Psychiatric Rating Scale scores) from baseline compared with placebo (Potkin *et al.* 2008).

In Study 3, patients selected according to the previously described criteria were randomly assigned to receive iloperidone 12-16 mg/day ($n = 244$; 46% discontinued) or 20-24 mg/day ($n = 145$; 41% discontinued), risperidone 6-8 mg/day ($n = 157$; 29% discontinued), or placebo ($n = 160$; 46% discontinued). In this study, the iloperidone 12-16 mg/day dosage failed to separate from placebo (Potkin *et al.* 2008).

A combined analysis of all three studies was performed to eliminate the impact of early discontinuations (i.e., those occurring in the initial 2 weeks of the studies, during which the drug reaches steady state). When the analysis was restricted to patients who had remained in double-blind treatment for at least 2 weeks ($n = 1,553$), it showed that each of the iloperidone dosage ranges (4-8, 10-16, and 20-24 mg/day) separated significantly from placebo (Potkin *et al.* 2008).

A 4-week double-blind study (Cutler *et al.* 2008) evaluated the efficacy of iloperidone 24 mg/day against that of placebo and of ziprasidone 160 mg/day in patients with acute exacerbation of schizophrenia by measuring change from baseline in the PANSS-T score and the PANSS positive, negative, and general psychopathology scale scores; the Calgary Depression Scale for Schizophrenia (CDSS) score; and the Clinical Global Impression--Severity (CGI-S) score. Patients receiving iloperidone showed significantly greater reductions on PANSS-T scores at 4 weeks compared with those receiving placebo. Although both iloperidone and ziprasidone produced significantly greater improvement on PANSS negative and positive and CGI-S scores compared with placebo, none of the drugs produced significant improvement on PANSS general psychopathology scores, nor did any drug affect CDSS scores.

Kane *et al.* (2008) conducted a long-term efficacy analysis using data from patients who had completed the 6-week double-blind phase of the three pivotal studies described previously. Patients who had at least a 20% reduction in PANSS-T scores and a CGI score of less than 4 and who had received at least one dose of long-term-phase medication were randomly assigned to iloperidone or haloperidol for 48 weeks of double-blind maintenance treatment (mean dosage at endpoint was 12.5 mg/day for both drugs). The primary efficacy variable was relapse (defined as an increase of [?] 25% in the PANSS score). Differences between the iloperidone group and the haloperidol group in time to relapse were not significant--63.6% of patients in both groups completed the long-term phase of the trial.

Cutler *et al.* (2013) reported on a 25-week open-label extension study. More than 58% of patients discontinued iloperidone. Overall improvement was seen in 80% of patients.

Weiden *et al.* (2014) reported on a 12-week trial in which patients with schizophrenia who were taking risperidone, olanzapine, or aripiprazole but were experiencing problems with tolerability or efficacy were switched to iloperidone ([?] 12 mg twice daily) via random assignment to either immediate cessation of the original drug or gradual down-titration. The results were similar across all groups, and the two switching strategies yielded comparable efficacy and tolerability.

A 24-week study of iloperidone (Weiden *et al.* 2016) demonstrated its efficacy as a maintenance treatment for schizophrenia, with a reduction in relapse with typical treatment dosages between 12 mg/day and 20 mg/day. A review of the relative potency and dose equivalency of iloperidone dosages suggested that 20 mg/day of iloperidone represents the 95% effective dose of this drug (Leucht *et al.* 2020). Dose equivalency to 1 mg/day of risperidone was estimated at 3.22 mg/day of iloperidone. In a systematic review and network meta-analysis of placebo-controlled and head-to-head randomized controlled trials of antipsychotic drugs, iloperidone was found to induce moderate change in positive symptoms and minimal change in negative symptoms for people with schizophrenia (Huhn *et al.* 2019).

Pharmacogenetic Studies

Clinical trials of iloperidone have sought to establish the drug's pharmacogenetic characteristics (Volpi *et al.* 2009a, 2009b) by exploring the relationship between its efficacy and various candidate genes related to dopamine receptors, dopamine b-hydroxylase, the serotonin$_{1B}$ receptor, and ciliary neurotrophic factor (CNTF). CNTF is a cytokine in the interleukin 6 cytokine family that suppresses noradrenergic and serotonergic function (Galter and Unsicker 1999). A null mutation in *CNTF* leads to a non-G/G rs1800169 genotype that cannot produce a functional protein and has been linked to an increased risk of psychosis (Thome *et al.* 1996). However, a meta-analysis involving more than 1,000 patients and a similar number of control subjects (Lin and Tsai 2004) found no association between *CNTF* and schizophrenia risk.

In a 4-week randomized, placebo-controlled study in 417 patients genotyped for *CNTF*, 279 patients received iloperidone and 138 received placebo (Lavedan *et al.* 2008). Iloperidone produced significantly greater improvement on symptom scores versus placebo in patients with an active

CNTF gene, whereas patients with the CNTF null allele showed no greater response to iloperidone than to placebo.

In a whole-genome study of 407 patients from the same sample, of whom 218 patients received iloperidone, six single-nucleotide polymorphisms (SNPs) associated with iloperidone efficacy were identified (Volpi *et al.* 2009b). The identified loci included SNPs of the neuronal PAS domain protein 3 gene (*NPAS3*); of the XK, Kell blood group complex subunit-related family, member 4 gene (*XKR4*); of the tenascin-R gene (*TNR*); of the glutamate receptor, ionotropic, AMPA 4 gene (*GRIA4*); of the glial cell line-derived neurotrophic factor receptor alpha 2 gene (*GFRA2*); and of the nudix hydrolase 9 pseudogene 1 (*NUDT9P1*) located in the chromosomal region of the serotonin receptor 7 gene (*HTR7*). More than 75% of the iloperidone-treated patients in the group with the optimal genotype combinations showed [?] 20% symptom improvement, whereas only 37% of patients with other genotypes showed [?] 20% improvement.

Another whole-genome association study (Volpi *et al.* 2009a) was conducted in 183 patients with schizophrenia who received an electrocardiogram on day 14 of treatment with iloperidone, after the drug had reached steady state. DNA polymorphisms associated with QT prolongation were found in six loci, including *CERKL*, thought to be part of the ceramide pathway; *SLCO3A1*, which encodes organic anion-transporting polypeptides; various genes involved in myocardial infarction (*PALLD*), cardiac structure and function (*BRUNOL4*), and cardiac development (*NRG3*); and an SNP on *NUBPL* with unknown function. Each SNP defined two genotype groups associated with a low mean QT interval change or a higher mean QT interval prolongation.

Although these findings have attracted considerable interest from the field, pharmacogenomic approaches to drug optimization need to be tested further in larger studies before these findings can be of clinical use. Nevertheless, the incorporation of pharmacogenetic testing into the regulatory registration trials of this drug represents an important new aspect of psychopharmacological drug development.

Other Indications

Little information is available on the use of iloperidone in patients with first-episode psychosis. Similarly, there are no studies to inform the use of iloperidone in patients with treatment-refractory schizophrenia. There is no information on the efficacy or tolerability of iloperidone in patients with comorbid substance use disorders. Information on the use of iloperidone to treat other comorbid conditions and/or other primary psychiatric and neuropsychiatric disorders is scant. An open-label pilot study of iloperidone given over 5 months to patients with bipolar disorder with mixed features showed efficacy in treating mood symptoms, both manic and depressive (Singh *et al.* 2017). Given the paucity of data to guide treatment, off-label use of this drug cannot be recommended.

Side Effects and Toxicology

Common Adverse Events in Early Studies

The safety of iloperidone in short-term studies was examined in a pooled analysis of the three 6-week Phase II studies of acute schizophrenia ($N =$ 1,943) conducted between 1998 and 2002 (Potkin *et al.* 2008). A total of 1,912 patients received at least one dose of study medication and were included in this pooled analysis. The safety cohort included 440 patients taking placebo, 463 taking iloperidone 4-8 mg/day, 456 taking iloperidone 10-16 mg/day, 125 taking iloperidone 20-24 mg/day, 118 taking haloperidol 15 mg/day, and 306 taking risperidone 4-8 mg/day. The most common treatment-related adverse events associated with iloperidone across all three dosage groups were dizziness, dry mouth, somnolence, and dyspepsia (Table 32-2).

TABLE 32-2. Safety profile of iloperidone in short-and long-term studies: adverse events

occurring in at least 5% of patients in any active-treatment group

[b] Long-term (46 weeks) maintenance treatment (mean dosage at study end was 12.5 mg/day for both drugs).

Source. Adapted from Kane *et al.* 2008 and Weiden *et al.* 2008.

With respect to available data from long-term studies, three prospective multicenter studies--each with a 6-week stabilization period followed by a 46-week double-blind maintenance phase--inform understanding of iloperidone's longer-term tolerability (Kane *et al.* 2008; see Table 32-2). Patients were randomly assigned to receive either iloperidone 4-16 mg/day or haloperidol 5-20 mg/day. Among the 1,644 patients who underwent random assignment and the 1,326 who completed the 6-week stabilization period, 473 (iloperidone: 359, haloperidol: 114) were included in the long-term efficacy analysis and 489 (iloperidone: 371, haloperidol: 118) were included in the safety analysis. The most common adverse events reported for iloperidone were insomnia, anxiety, and headache.

Extrapyramidal Side Effects

In a pooled analysis of pivotal short-term trials comparing iloperidone (4-8 mg/day, 10-16 mg/day, and 20-24 mg/day), risperidone, and haloperidol, all iloperidone dosages demonstrated significant improvement (as measured by overall EPS ratings from baseline to endpoint on the Extrapyramidal Symptom Rating Scale [ESRS] [Chouinard and Margolese 2005]). By comparison, there was no significant change with risperidone and significant worsening with haloperidol. Akathisia items on the ESRS all showed significant improvement from baseline for iloperidone at the 10-16 mg/day and 20-24 mg/day dosage ranges (Nair *et al.* 2020; Weiden *et al.* 2008). The low EPS profile of iloperidone is an advantage clinically, even in this era of prescribing predominantly SGAs, in which one's risk of EPS is much lower than in the past (Weiden 2012). Moreover, the absence of a dose-related increase in EPS across dosage ranges in clinical trials of iloperidone is conspicuous and encouraging.

Orthostatic Hypotension

In view of its antagonism of a_1-adrenergic receptors, iloperidone possesses the potential for autonomic side effects. In its clinical trials program, iloperidone was associated with decreases in supine and standing systolic and diastolic blood pressure in all dosage groups. Decreases in blood pressure were mostly observed within the first week of treatment and were generally not sustained. Orthostatic hypotension was observed more frequently in all active-treatment groups (iloperidone, risperidone, and haloperidol) than in the placebo group. Sustained orthostatic hypotension was observed in 0.4% ($n = 2$), 3.8% ($n = 17$), and 4.8% ($n = 6$) of patients receiving iloperidone 4-8 mg/day, 10-16 mg/day, and 20-24 mg/day, respectively. According to the manufacturer's full prescribing information (Vanda Pharmaceuticals 2016), iloperidone must be initiated slowly and gradually so as to avoid orthostatic hypotension, with a starting dosage of 1 mg twice daily, increasing to 2 mg, 4 mg, 6 mg, 8 mg, 10 mg, and 12 mg twice daily on days 2, 3, 4, 5, 6, and 7, respectively, to a target dosage range of 12-24 mg/day. Clinicians should therefore pay particular attention to dizziness early in treatment with iloperidone. It is also important to go even slower with initial titration in patients who may be at risk for postural hypotension (Weiden 2012).

Weight Gain and Metabolic Effects

One of the potential advantages of iloperidone could be its profile with respect to metabolic issues and weight gain (De Hert *et al.* 2012; Tarazi and Stahl 2012). Compared with patients receiving placebo, patients receiving iloperidone exhibited a small but statistically significant increase in weight across all dosages. For all patients completing the respective studies, the mean weight gain was 2.4 kg in each iloperidone dosing group. Clinically significant weight gain (defined as a [?] 7% increase in body weight from baseline) occurred in 12.3% of subjects in all iloperidone groups (Weiden *et al.* 2008). The majority of the weight gain occurred within the first 6 weeks of the studies (6.4%). Long-term treatment with iloperidone also produced slight increases in total cholesterol, triglycerides, and glucose levels (Kane *et al.* 2008). Increased prolactin levels were not observed in the pooled analysis of the three 6-week trials. The prescribing information (Vanda Pharmaceuticals 2016), however, emphasizes findings from the 4-week iloperidone versus ziprasidone versus placebo trial, in which 26% of subjects receiving iloperidone, versus 12% of those receiving placebo, exhibited elevated plasma prolactin levels. Thus, the relatively more favorable weight and metabolic profiles of iloperidone constitute a distinction that might guide the selection and use of iloperidone in particular patient groups (Weiden 2012).

However, in a provocative preclinical study in which rats were exposed to iloperidone, asenapine, or olanzapine (Boyda *et al.* 2013), the iloperidone-exposed rats developed glucose intolerance. In a double-blind study in which healthy human volunteers were randomly assigned to receive olanzapine, iloperidone, or placebo for 1 month, iloperidone and placebo did not induce any significant weight gain, lipid elevation, or alteration in insulin metabolism compared with olanzapine (Ballon *et al.*

2018). In a retrospective study, 64 outpatients treated with iloperidone for a mean of 236 days had significant within-group weight gain at 12 weeks (4.54 lb [2.06 kg]; $P < 0.01$) and up to 1 year (5.13 lb [2.33 kg]; $P = 0.02$) compared with olanzapine, which yielded an average weight gain of 10.3 lb (4.67 kg; ($P < 0.01$) following treatment up to 1 year (Greger *et al.* 2021).

QT Interval Prolongation

With respect to potentially life-threatening side effects, there was evidence of significant QT/QTc interval prolongation across all iloperidone groups in the drug's pivotal study program, and this potential drug effect was a focus of a review by the FDA. Specifically, the least squares mean change in QTc interval from baseline to endpoint in these studies was 2.9 milliseconds, 3.9 milliseconds, and 9.1 milliseconds for iloperidone 4-8 mg/day, 10-16 mg/day, and 20-24 mg/day, respectively. It is noteworthy that no deaths or serious arrhythmias attributable to QT prolongation occurred in these studies (Weiden 2012; Weiden *et al.* 2008). Potkin *et al.* (2013) examined the incidence of QTc prolongation in patients randomly assigned to receive iloperidone, quetiapine, or ziprasidone. To further test for metabolic inhibition, there was a period of coadministration of paroxetine and paroxetine plus ketoconazole. These conditions resulted in QTc intervals of 60 milliseconds or greater in approximately 10% of patients receiving iloperidone. However, no patients had clinical symptoms, and none had a QTc interval that reached or exceeded 500 milliseconds. The mechanism of QT/QTc interval prolongation by antipsychotic drugs is attributed to blockade of the human ether-a-go-go-related gene (*hERG*), which encodes a subunit of the potassium ion channel (Silvestre and Prous 2007). Vigneault *et al.* (2012) demonstrated that iloperidone blocks *hERG*, resulting in a 42.7-millisecond QT interval prolongation after administration of a single oral dose in guinea pigs. Lee *et al.* (2021) further studied the effect of iloperidone on *hERG* 1A/3.1 (a K^+ channel specific to primates) and found that iloperidone inhibits *hERG* 1A/3.1 currents by binding to the open states of the channels but does not disrupt the membrane trafficking or the surface membrane expression of *hERG* 1A channel protein. Further research is needed to translate these findings to clinical practice.

Contraindications

According to the manufacturer's prescribing information (Vanda Pharmaceuticals 2016), iloperidone should be avoided in combination with other drugs that are known to prolong the QTc interval, a group that includes Class Ia (e.g., quinidine, procainamide) and Class III (e.g., amiodarone, sotalol) antiarrhythmic medications, antipsychotic medications, and antibiotics. This prohibition makes sense, given iloperidone's metabolism through these cytochrome pathways. In addition, it is recommended that iloperidone be avoided in persons with congenital long QT syndrome or cardiac arrhythmias.

Like all other SGAs, iloperidone carries a black box warning regarding the increased mortality risk associated with the use of antipsychotic drugs in elderly patients with dementia-related psychosis. That said, iloperidone is not approved for the treatment of patients with dementia-related psychosis, and its use in the elderly should be avoided pending future clinical trials.

Conclusion

Iloperidone is an FDA-approved antipsychotic with proven efficacy in the treatment of schizophrenia. Recent reviews suggest that it may be less efficacious than other SGAs for treating schizophrenia. In a systematic review and network meta-analysis of placebo-controlled and head-to-head randomized controlled trials of antipsychotic drugs, iloperidone was found to induce moderate change in positive symptoms and minimal change in negative symptoms for people with schizophrenia (Huhn *et al.* 2019). However, there are insufficient data at present to substantiate this viewpoint. The current lack of short-term intramuscular and long-acting intramuscular formulations also limits the broader applicability of this medication in clinical practice. That said, its side-effect profile could perhaps favor preferential use in patients who experience weight gain from other antipsychotics. Its use to treat mood disorders and other conditions is not FDA approved, and clinical studies are under way in such areas.

CHAPTER 33

Lurasidone

Philip D. Harvey, Ph.D.

Lurasidone (Latuda) is a more than 10-year-old addition to the atypical antipsychotic class. It received FDA approval for the treatment of schizophrenia in October 2010 and is currently approved for the treatment of adults and adolescents (ages 13-17 years). In June 2013, lurasidone also received FDA approval for the treatment of bipolar depression in adults as an adjunctive therapy with lithium or valproate. Lurasidone now has an approved indication for monotherapy treatment of major depressive episodes associated with bipolar I disorder (bipolar depression) in adults and pediatric patients (ages 10-17 years).

Like all currently registered antipsychotic medications, lurasidone is a dopamine$_2$ (D_2) receptor antagonist. In addition, this compound is a full antagonist at the serotonin$_{2A}$ (5-HT_{2A}) receptor, similar to many other atypical antipsychotic medications. Lurasidone has other receptor affinities that may contribute to additional beneficial or adverse effects. Because lurasidone is newer than medications such as risperidone or olanzapine, its comparative literature is more limited than that of other medications, although lurasidone's approved indication for bipolar depression has led to published research in adults with bipolar depression as well as research examining lurasidone's efficacy and safety in children with schizophrenia or bipolar disorder. A current interesting line of investigation, with benefits for children and adolescents, is lurasidone's potential utility in the treatment of bipolar depression with mixed (subsyndromal hypomanic) features.

In this chapter, I review the pharmacological properties and efficacy basis of lurasidone, the side effects and adverse events seen in pivotal critical follow-up studies, and other features of the compound that may prove to be important in clinical applications of this agent. I also consider the question of what seems unique about lurasidone compared with other available antipsychotic medications.

Structure-Activity Relations and Pharmacological Properties

Receptor Binding Profile

Lurasidone belongs to the chemical class of benzisothiazole derivatives (Figure 33-1). The compound is a full antagonist at D_2 and 5-HT_{2A} receptors, a profile it shares with other atypical antipsychotics. Lurasidone also has high affinity for $serotonin_7$ (5-HT_7) receptors, with in vitro affinity for 5-HT_7 being relatively higher than that shown by the drug for D_2 and 5-HT_{2A} receptors. Lurasidone is a partial agonist at $serotonin_{1A}$ (5-HT_{1A}) receptors (Ishibashi *et al.* 2010) and has moderate affinity for noradrenergic receptors. Lurasidone's minimal affinity for a_1-adrenergic receptors would be expected to convey a reduced risk for orthostatic hypotension in comparison with compounds that have higher affinity for this receptor. Lurasidone appears to have weak affinity for $serotonin_{2C}$ receptors and no affinity for $histamine_1$ receptors, a profile that should carry relatively low risk for weight gain. Lurasidone lacks affinity for muscarinic acetylcholine M_1 receptors, which suggests reduced risk for cholinergic cognitive deficits and other side effects.

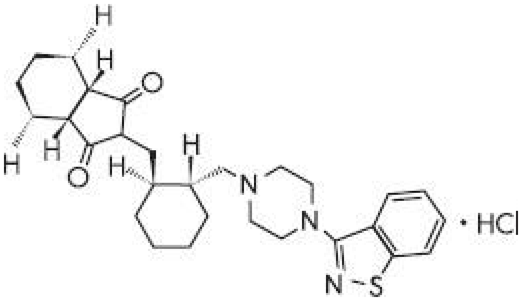

FIGURE 33-1. Chemical structure of lurasidone.

Pharmacokinetics and Dosing

Lurasidone is rapidly absorbed and reaches peak concentrations within 3 hours for the lowest effective antipsychotic dose, 40 mg. Steady state is reached within 7 days (Sunovion Pharmaceuticals 2013). The pharmacokinetics of lurasidone are dose proportional within a total daily dosage of 20-160 mg. The molecule is metabolized in the liver via the cytochrome P450 (CYP) 3A4 enzyme system, which leads to the conclusion that lurasidone should not be used in the presence of strong inducers (e.g., rifampin) or inhibitors (e.g., ketoconazole) of CYP3A4. Lurasidone does show a food effect. A study examining food effects on lurasidone concentrations found that taking the drug with meals containing 350 calories or more, with either low or high fat content, led to a doubling of the bioavailability of lurasidone compared with dosing during fasting (Chiu *et al.* 2010).

The recommended starting dosage of lurasidone is 40 mg/day, with the dose taken concurrently with at least 350 calories of food. Dosages up to 160 mg/day in adults and up to 80 mg/day in adolescents are currently approved for treatment of schizophrenia,

and dosages up to 120 mg/day in adults and up to 80 mg/day in pediatric patients are approved for bipolar depression. As previously noted, lurasidone should not be used by patients taking medications that are strong metabolic inducers or inhibitors of CYP3A4. Dosage adjustment is recommended if lurasidone is administered with a moderate CYP3A4 inhibitor. Also, grapefruit and grapefruit juice should be avoided by individuals taking lurasidone. There are no suggested dosage adjustments based on gender, ethnicity, or smoking. In individuals with moderate to severe renal impairment, the recommended starting dosage is 20 mg/day, and dosages should not exceed 80 mg/day. For those with moderate to severe hepatic impairment, the recommended starting dosage is also 20 mg/day, with a maximum dosage of 40 mg/day for moderate hepatic impairment and 80 mg/day for severe impairment. Lurasidone is currently available in 20-, 40-, 60-, 80-, and 120-mg tablets (Sunovion Pharmaceuticals 2013). In a study examining the effects of different lurasidone dosages among hospitalized patients with acute schizophrenia, lurasidone 20 mg/day failed to separate from placebo (Loebel *et al.* 2016).

Lurasidone lacks a requirement for initial dosage titration and appears to require minimal adjustment and tinkering. Having a starting dose with substantial efficacy is a strong point for many patients. Food effects are an issue, given that optimal exposure requires the medication to be taken with at least 350 calories of food (with no minimum fat content specified); however, the lack of a need for titration and the uncomplicated requirements for suitable meals make it easier to apply this treatment to patients who may be challenged in their ability to adhere to complex regimens.

Efficacy and Tolerability

Pivotal Registration Trials in Schizophrenia

In the standard drug development program, lurasidone at daily dosages of 40 mg, 80 mg, and 120 mg was compared with placebo in four separate studies (Meltzer *et al.* 2011; Nakamura *et al.* 2009; Nasrallah *et al.* 2013; Ogasa *et al.* 2013), with several different dosing and comparator strategies. A fifth study (Loebel *et al.* 2013) added a 160-mg/day dosage. Citrome (2011a, 2011b) reviewed data based on conference presentations for the schizophrenia development program. Patients ranged in age from 18 to 74 years and were symptomatic with an acute exacerbation of psychosis. In the early clinical studies, the dosage that most consistently separated from placebo was 80 mg/day, although 40 mg/day and 120 mg/day did as well in some trials.

Comparative Efficacy Studies

Schizophrenia

Four blinded and randomized studies compared lurasidone with other agents in the treatment of schizophrenia. In the first study (Potkin *et al.* 2011), lurasidone was compared with ziprasidone in a 3-week randomized trial in 301 patients with schizophrenia. Both treatments improved symptoms as measured by the Positive and Negative Syndrome Scale (PANSS), and there were no significant differences in endpoint PANSS scores.

In the second study (Meltzer *et al.* 2011), lurasidone was compared with olanzapine in clinically unstable patients with schizophrenia who had been admitted to inpatient care. Both olanzapine and lurasidone were superior to placebo for clinical response. In addition, weight gain was significantly greater with olanzapine than with either lurasidone or placebo, whereas rates of akathisia were significantly higher in the lurasidone group compared with the other two groups.

In the third study (Loebel *et al.* 2013), two dosages of lurasidone (80 mg/day and 160 mg/day) were compared with quetiapine extended release (XR) 600 mg/day and placebo in inpatients experiencing an acute exacerbation of schizophrenia. Both lurasidone (at both dosages) and quetiapine separated from placebo, and weight gain and sedation/sleepiness were more frequent with quetiapine than with either dosage of lurasidone.

In the fourth study (Citrome *et al.* 2012), clinically stable patients with schizophrenia were randomly assigned to receive either risperidone or lurasidone and were followed for 12 months to assess potential differences in long-term safety. Findings included greater weight gain with risperidone, minimal differences between lurasidone and risperidone in efficacy, and no differences between the two agents in relapse rates. All-cause discontinuation rates were higher for lurasidone, possibly because of slight elevations in nausea in the lurasidone group.

Bipolar Depression

Two randomized, placebo-controlled trials of lurasidone were conducted in patients with bipolar depression. In the first study (Loebel *et al.* 2014b [monotherapy]), lurasidone at two different dosage ranges (20-60 mg/day and 80-120 mg/day) was compared with placebo. Both dosage ranges separated from placebo, with similar effect sizes. In the second study (Loebel *et al.* 2014a [adjunctive therapy]), lurasidone 20-120 mg/day was added to stable treatment with either valproate or lithium. Statistically significant separation from placebo was found. Lurasidone treatment was administered at a mean modal dosage of 75 mg/day, which translates to an available dosage of 80 mg/day. The results of these two studies led to lurasidone's approval by the FDA for both augmentation of lithium or valproate therapy and monotherapy of bipolar depression in June 2013.

In an additional post hoc analysis of the results of the monotherapy study, McIntyre *et al.* (2015) reported that lurasidone was effective in the treatment of a newly introduced DSM-5 (American Psychiatric Association 2013) entity--the specifier "with mixed features," which can be applied to depressive and bipolar disorders. In this study, the presence of mixed (subsyndromal hypomanic) features was defined as a Young Mania Rating Scale (Young *et al.* 1978) score of 4 or greater at study baseline. Fifty-six percent of the patients in the study (272 of 485) were identified as having depression with mixed features. Among the patients with mixed features, 182 received lurasidone (active treatment) and 90 received placebo. Lurasidone's efficacy in treating depression in patients with and without mixed features was essentially equivalent: 15.7-point decreases in Montgomery-Asberg Depression Rating Scale (Montgomery and Asberg 1979) scores were seen for patients without mixed features, and 15.2-point decreases were found for those with mixed features. Among patients who received active treatment, 82% of those without mixed features completed the trial, compared with 73% of those with mixed features. These data indicate that the presence of mixed features in bipolar depression should not be viewed as a contraindication to treatment with lurasidone.

In a study targeted at depression with mixed features, patients selected for the presence of major depressive disorder as defined in DSM-IV-TR (American Psychiatric Association 2000) and two or three manic symptoms were randomly assigned to receive lurasidone (n = 109) or placebo (n = 100) for a 6-week trial (Suppes *et al.* 2016). Lurasidone was superior to placebo, leading to a 20.5-point change in score on the Montgomery-Asberg Depression Rating Scale for active treatment compared with a 13-point change for placebo ($P < 0.001$; effect size $d = 0.80$). Completion rates were similar for active treatment and placebo (94% and 85%, respectively), and the remission rate was 49% for active treatment. Switch into mania did not occur with lurasidone treatment, and patients who received lurasidone manifested a 7-point decrease in their Young Mania Rating Scale scores. These data suggest efficacy for lurasidone in the treatment of major depressive disorder with mixed features as well as bipolar depression.

Efficacy in Children and Adolescents

Several studies have examined the safety and efficacy of lurasidone in children and adolescents with the conditions for which the drug is approved to treat adults. Goldman *et al.* (2017) reported on a three-arm efficacy study of participants with schizophrenia ages 13-17 (N = 327). Lurasidone at dosages of 40 mg/day or 80 mg/day was compared with placebo. Both dosages separated from placebo, with effect sizes of d = 0.48 or better on PANSS total scores. Safety outcomes were comparable to those in adults with schizophrenia, in that weight gain was < 0.50 kg for the 80 mg/day group. Only one participant discontinued because of akathisia. A 2-year open-label follow-up of these participants (Correll *et al.* 2022) found that the mean changes in weight from the double-blind baseline at week 52 and week 104 were + 3.3 kg and + 4.9 kg, respectively, compared with an expected weight gain of + 3.4 kg and + 5.7 kg (based on Centers for Disease Control and Prevention [CDC] sex-and age-matched normative data).

DelBello *et al.* (2017) evaluated the efficacy and safety of lurasidone (20-80 mg/day) versus placebo among 10-to 17-year-olds with a bipolar I disorder diagnosis who were experiencing a major depressive episode. Children's Depression Rating Scale scores of patients in the active treatment group separated from scores in the placebo group starting at week 2 of the 6-week treatment trial. Symptoms related to extrapyramidal side effects (EPS) did not differ markedly between the groups, and rates of switching into mania were essentially identical across the samples (6.9% [lurasidone] vs. 7.0% [placebo]). Finally, short-term weight gain was minimal in the study, with an average gain of 0.74 kg in the lurasidone group and 0.44 kg in the placebo group.

A 2-year open-label follow-up (DelBello *et al.* 2021) of the participants in the 2017 study revealed continued clinical improvement and, again, very modest weight gain: the mean changes in weight from the double-blind baseline were + 4.25 kg at week 52 (vs. expected weight gain of + 3.76 kg [based on CDC sex-and age-matched normative data]) and + 6.75 kg at week 104 (vs. expected weight gain of + 6.67 kg). Changes in depression scores from the open-label baseline were [?]13.4 at week 52 and [?]16.4 at week 104 ([?]11.3 at last-observation-carried-forward endpoint). Only 10% of participants discontinued treatment because of an adverse event.

Summary of Efficacy and Tolerability Data

The risk-benefit evaluation for lurasidone suggests a lower potential for metabolic consequences and QTc prolongation combined with a slightly higher risk of EPS and akathisia compared with some of the other atypical antipsychotic medications. Prolactin elevation appears to be minimal within the approved dosage range. Given the limited clinical experience with lurasidone, it may be premature to target an optimal patient for this medication; however, the reduced metabolic consequences of lurasidone would seem to be a very strong point. Patients who are extraordinarily vulnerable to EPS may require close monitoring.

Lurasidone's efficacy in treating schizophrenia relative to other agents was examined in four active comparison studies (Citrome *et al.* 2012; Loebel *et al.* 2013; Meltzer *et al.* 2011; Potkin *et al.* 2011), none of which found lurasidone to be inferior. It is not yet possible to assess lurasidone's relative efficacy in treating bipolar depression, given the absence of comparative trials to date. However, these four active comparison studies showed that lurasidone was at least as effective as placebo in treating children and adolescents with schizophrenia or bipolar depression, and that lurasidone's weight gain parameters in pediatric populations were very similar to those in adults.

Side Effects and Safety

Class Warnings

The typical class warnings are present in the lurasidone label (Sunovion Pharmaceuticals 2013), including the black box warning about increased stroke risk in elderly persons and a variety of other class warnings regarding neuroleptic malignant syndrome, tardive dyskinesia, diabetes, hyperlipidemia, weight gain, glucose abnormalities, hyperprolactinemia, agranulocytosis, suicide, and seizures. Lurasidone has no warning for QTc alteration; a dedicated cardiac safety study (referenced in the package insert) found no evidence of QTc prolongation with lurasidone treatment.

Adverse Event Reports

Safety information is available from the manufacturer's safety database (see also www.sunovionmedical.com/therapeutic_areas/psychiatry.html). Dose-related adverse effects that separated from placebo included somnolence, akathisia, and EPS (as measured by total scores on clinical rating scales for EPS). It is notable that weight and metabolic parameters were only minimally affected in patients with schizophrenia or bipolar depression in clinical trials. Although short-term changes in cholesterol, triglycerides, and glucose are likely to be attributable to the transition from medications with more substantial adverse profiles in these domains, the weight gain data for lurasidone are very noticeable and consistent.

Promising Features

Minimal Weight Gain

Lurasidone appears to have the promise of weight neutrality. Weight gain in pooled 6-week studies across doses was 0.75 kg; in the pooled 12-month database from extension studies, patients lost an average of 0.4 kg (Meyer *et al.* 2015). These statistics compare favorably with those for other antipsychotics in wide clinical use (see the review

by Citrome [2011b]). It is important to note that specific populations outside the current label may have a greater risk for weight gain compared with the typical patient with chronic schizophrenia in these trials. Data are not yet available for lurasidone's profile in the long-term treatment of bipolar depression. Nevertheless, the suggestion of no weight gain after a year's treatment, even for patients who may have gained weight with previous treatments, is quite promising.

Potential Cognitive Benefits

Basic Science Rationale

Compounds that interact with the 5-HT_7 receptor as their primary binding profile have historically been shown to produce beneficial cognitive effects in animal models (Ballaz *et al.* 2007). Furthermore, it is postulated that agents with partial agonist properties at the 5-HT_{1A} receptor may have potential benefit in regard to a reduction in flat affect and related negative symptoms in schizophrenia (Newman-Tancredi 2010).

Dizocilpine (MK-801) is a glutamate receptor antagonist that is used to induce cognitive impairments in healthy individuals that are quite similar to those seen in schizophrenia. Like other *N*-methyl-D-aspartate antagonists, MK-801 is capable of inducing deficits in memory and problem-solving. Given that *N*-methyl-D-aspartate antagonists such as ketamine and phencyclidine can induce a reliable analog of schizophrenia in healthy people (and exacerbate psychosis in patients with schizophrenia), such manipulations have more intrinsic validity than cholinergic manipulations, such as scopolamine challenge. In rats, lurasidone has shown the potential to reverse MK-801-induced learning and memory deficits in the passive avoidance test (Ishiyama *et al.* 2007) and the Morris water maze (Enomoto *et al.* 2008).

Research using analogs of cognitive impairment derived from animal models has notoriously failed to yield paradigms with adequate translational relevance to the specific cognitive domains affected in schizophrenia, particularly in terms of reliably predicting beneficial cognitive effects associated with pharmacological treatment (Harvey 2009). A possible reason for this failure may be that the adverse influences on human cognition of dopamine D_2 receptor antagonism associated with antipsychotic treatment may override the influences of a secondary receptor profile, preventing its beneficial effects from being realized (Harvey and McClure 2006). For example, ziprasidone, a partial agonist at the 5-HT_{1A} receptor, has never demonstrated greater cognitive benefit than antipsychotics that do not interact with that receptor (e.g., olanzapine [Harvey *et al.* 2004]). Thus, clear evidence of cognitive enhancement in patients with schizophrenia treated with the medication of interest, compared with other treatments in similar populations, is the bottom-line requirement for demonstration of meaningful cognitive benefit.

Studies in Schizophrenia and Bipolar Disorder

Three published studies in patients with schizophrenia have addressed the issue of lurasidone's cognitive benefit compared with that of other antipsychotics (Harvey *et al.* 2011, 2013, 2015), and a single study has examined cognitive benefits in bipolar disorder (Yatham *et al.* 2017).

The first study, which was conducted during the early development of lurasidone, was a 3-week double-blind, randomized head-to-head comparison of lurasidone and

ziprasidone in generally clinically stable outpatients with schizophrenia (Harvey *et al.* 2011). At the time this study was conducted, no U.S. patients had ever been exposed to lurasidone. Patients were selected for being naive to treatment with ziprasidone as well. The study examined changes in performance on a neuropsychological assessment consisting of most of the tests in the widely used Measurement and Treatment Research to Improve Cognition in Schizophrenia (MATRICS) Consensus Cognitive Battery (Nuechterlein *et al.* 2008) and an interview-based assessment of cognitive functioning, the Schizophrenia Cognition Rating Scale (SCoRS; Keefe *et al.* 2006). The study found that lurasidone was associated with improvements on neuropsychological tests that were generally consistent with practice effects (Harvey *et al.* 2011). There was one exception, processing speed, which manifested relatively greater improvement with lurasidone than with ziprasidone. However, the improvements seen with lurasidone on the SCoRS were double the size of the improvements seen on the neuropsychological assessments and were nearly significantly larger than the improvements associated with ziprasidone. These results cannot be attributed to practice effects, given that the SCoRS is an interview, not a performance-based measure. Furthermore, the fact that the differential effects of lurasidone and ziprasidone were nearly significant ($P < 0.06$) argues against a generalized bias effect, because the lurasidone effects were clearly larger.

The second study (Harvey *et al.* 2013) compared two dosages of lurasidone (80 mg/day and 160 mg/day) with 600 mg/day quetiapine XR and placebo. This double-blind, placebo-controlled trial was conducted in patients experiencing an acute exacerbation of psychosis. Lurasidone 160 mg/day was compared with placebo, quetiapine XR, or lurasidone 80 mg/day over a 6-week period, followed by a 6-month double-blind extension. Follow-ups were conducted at 3 and 6 months, and patients receiving placebo were switched to lurasidone at flexible dosages; patients taking quetiapine XR continued to receive the same treatment. The CogState Computerized Cognitive Battery (Pietrzak *et al.* 2009) and the University of California San Diego Performance-based Skills Assessment--Brief version (Mausbach *et al.* 2007; Patterson *et al.* 2001) were administered at baseline and at each assessment point. When patients who provided invalid baseline CogState data were censored from the analysis, lurasidone 160 mg/day separated from placebo on composite cognitive improvement at the 6-week endpoint, whereas lurasidone 80 mg/day and quetiapine XR did not.

Harvey *et al.* (2015) presented an analysis of the dose-response relationships of lurasidone compared with quetiapine XR during the full 6-month duration of the trial. The full sample, regardless of the validity of baseline performance, was examined at two follow-up assessments (at 3 and 6 months). Lurasidone at both dosages (80 mg/day and 160 mg/day) was found to be superior to quetiapine XR at both assessments (Harvey *et al.* 2015). Scores on the University of California San Diego Performance-based Skills Assessment--Brief version improved with all active treatments at each of the assessment time points, with no between-group differences in improvements.

Although these results clearly require replication, they suggest that lurasidone may have beneficial cognitive effects. In all three studies, performance-and interview-based assessments of functionally relevant cognitive processes showed treatment-related improvements. In the Harvey *et al.* (2013) study, the performance-based cognitive assessments also showed improvements that were superior to those seen with placebo or the active comparator. This superiority to the comparator was confirmed across all dosages of lurasidone in the Harvey *et al.* (2015) study. The sleepiness-inducing effects of quetiapine XR may have contributed to the difference between this compound and lurasidone (Loebel *et al.* 2014c); however, this would not explain the separation of lurasidone from placebo.

The Yatham *et al.* (2017) study in bipolar disorder was an open-label augmentation study that added lurasidone 20-80 mg/day (mean dosage 48 mg/day) to treatment as usual in a randomized, open-label study design. Participants who took lurasidone improved by an effect size of $d = 0.48$ on a modified version of the MATRICS Consensus Cognitive Battery, whereas participants who received treatment as usual showed an improvement with retesting of $d = 0.04$ ($P < 0.03$). However, adverse event were reported by 60% of participants in the lurasidone group, which suggests that augmentation therapy may be challenging from a safety perspective.

Conclusion

Lurasidone is a newer antipsychotic with some benefits compared with other available medications, including a low propensity for weight gain and reduced risk for metabolic side effects. Little of the published data have been supported by sources other than the sponsor of the medication. We will watch this medication carefully to continue to determine its benefit over time. Since the previous edition of this textbook was published, the efficacy of lurasidone in children and adolescents has been demonstrated for both current indications, and additional cognitive and long-term safety data have become available. No new safety concerns have emerged, and no new data raising questions about the drug's efficacy have appeared. As of 2023, lurasidone is now available as a generic medication in the United States, although in other countries around the world, such as Japan and China, the drug has several years of patent life remaining.

CHAPTER 34

Cariprazine

Leslie Citrome, M.D., M.P.H.

Cariprazine (Vraylar) was initially discovered by Gedeon Richter Ltd. as RGH-188 (Kiss *et al.* 2010) and was further developed by Forest Laboratories. It was approved by the FDA in 2015 for the treatment of schizophrenia and acute manic or mixed episodes associated with bipolar I disorder in adults (U.S. Food and Drug Administration 2015) and by the European Medicines Agency in 2017 for the treatment of schizophrenia under the brand name Reagila (European Medicines Agency 2017). In 2019, cariprazine received approval by the FDA for the treatment of depressive episodes associated with bipolar I disorder in adults (bipolar depression; U.S. Food and Drug Administration 2019). In 2022, cariprazine received FDA approval for use as an adjunct to antidepressants for the treatment of major depressive disorder in adults (U.S. Food and Drug Administration 2022). Cariprazine is available in capsule strengths of 1.5, 3.0, 4.5, and 6.0 mg; however, not all doses are applicable for all indications (Allergan 2022).

Although cariprazine, a piperazine/piperidine derivative, is the third dopamine receptor partial agonist antipsychotic to become generally available, it differs from the other two, aripiprazole and brexpiprazole, in several respects (Citrome 2015). These differences include an almost 10-fold higher affinity for dopamine type 3 (D_3) versus type 2 (D_2) receptors (Table 34-1), which has potentially important clinical implications for the treatment of negative symptoms of schizophrenia and regulation of mood. In addition, when titrating the dosage of cariprazine, the extended half-life of its major active metabolite, didesmethyl-cariprazine (DDCAR) (Figure 34-1), needs to be considered (Citrome 2018).

TABLE 34-1. Pharmacodynamic profiles of cariprazine, aripiprazole, and brexpiprazole: in vitro binding affinities for human receptors

			Affinity K_i^a (in vitro)		
Receptor[b]		**Activity**	**Cariprazine**	**Aripiprazole**	**Brexpiprazole**
Dopamine	D_3	Partial agonist	0.085	0.8	1.1
	D_{2L}	Partial agonist	0.49	0.34	0.30
	D_{2S}	Partial agonist	0.69		
Serotonin	5-HT_{1A}	Partial agonist	2.6	1.7	0.12
	5-HT_{2A}	Antagonist	18.8	3.4	0.47
	5-HT_{2B}	Antagonist	0.58	0.36	1.9
	5-HT_{2C}	Antagonist	134	15	34
	5-HT_7	Antagonist	111	39	3.7
Histamine	H_1	Antagonist	23.2	61	19
Adrenergic	a_{1A}	Antagonist	155	57	3.8

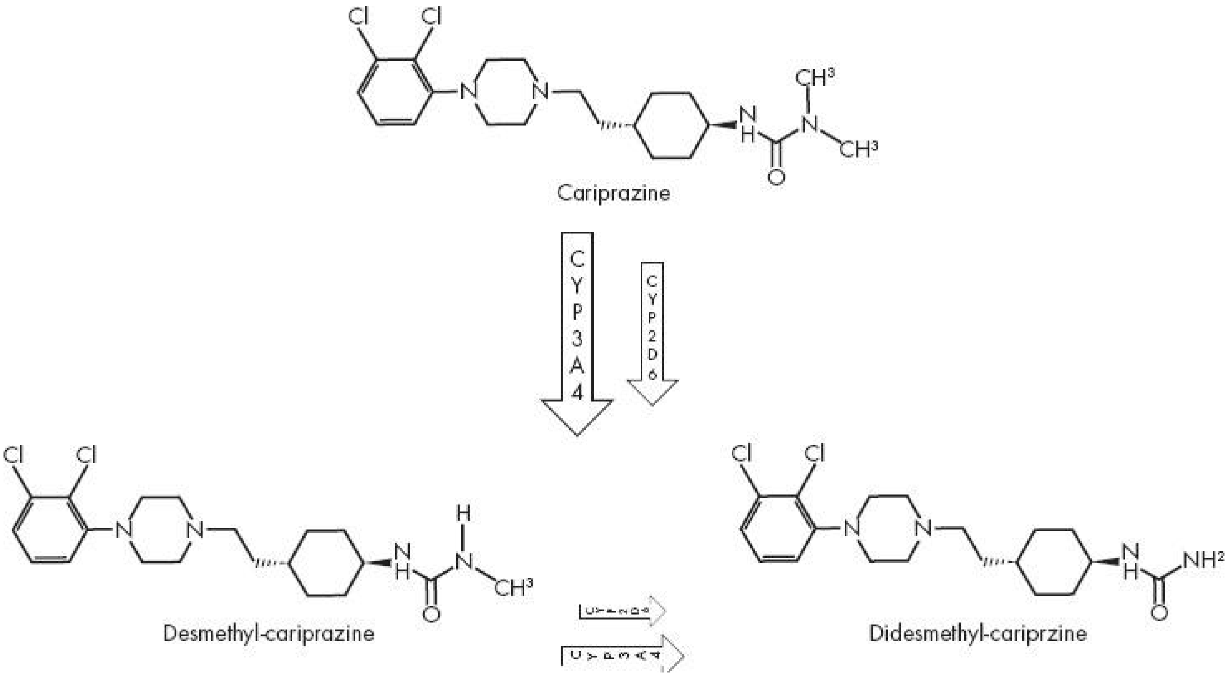

FIGURE 34-1. Chemical structures of cariprazine and its major metabolites, desmethyl-cariprazine and didesmethyl-cariprazine.

CYP = cytochrome P450.

Cariprazine is also being studied in adolescent patients (age 13-17 years) with schizophrenia (ClinicalTrials.gov identifier NCT03817502), in pediatric patients (age 10-17 years) with depressive episodes associated with bipolar I disorder (ClinicalTrials.gov identifier NCT04777357), and in pediatric patients (age 5-17 years) with irritability due to autism spectrum disorder (ClinicalTrials.gov identifier NCT05439616).

Pharmacodynamics

Structure

Cariprazine, also known as RGH-188 and MP-214, is 3-[4-{2-[4-(2,3-dichlorophenyl)piperazin-1-yl]ethyl}cyclohexyl]-1,1-dimethylurea (see Figure 34-1). The active ingredient is cariprazine hydrochloride, a compound synthesized and selected for development on the basis of its high selectivity for D_3 receptors over D_2 receptors (Kiss *et al.* 2010). Cariprazine has two clinically relevant active metabolites, desmethyl-cariprazine (DCAR) and DDCAR, whose pharmacology is like that of cariprazine (Kiss *et al.* 2019).

Receptor Binding Profile

Cariprazine is a potent D_3 and D_2 receptor partial agonist with preferential binding to D_3 receptors. This is a unique pharmacological profile among known antipsychotic medications (Kiss *et al.* 2010).

The theory behind the use of partial agonists, including cariprazine, is that these agents restore homeostatic balance to neurochemical circuits by 1) decreasing the effects of endogenous neurotransmitters (dopamine tone) in regions of the brain where their transmission is excessive, such as in the mesolimbic/striatal regions in schizophrenia or mania; 2) simultaneously increasing neurotransmission in regions where transmission of endogenous neurotransmitters is low, such as in the prefrontal cortex in schizophrenia; and 3) exerting little effect in regions where neurotransmitter activity is normal, such as in the pituitary gland.

Aripiprazole and brexpiprazole are also dopamine receptor partial agonists, with lower affinity for the dopamine D_3 receptor than for the D_2 receptor (Frankel and Schwartz 2017). In contrast, cariprazine has a six-to eightfold greater affinity for D_3 receptors than for D_2 receptors, with a specificity for D_3 receptors that is 3-10 times greater than aripiprazole's specificity for these receptors (Citrome 2015). There are other differences in the receptor-binding profiles of the three available dopamine receptor partial agonists, and these are outlined in Table 34-1. These profile differences can explain potential differences in tolerability among these choices. Moreover, the labeled indications for the three agents currently differ. In addition to its labeled indications for schizophrenia and for manic or mixed episodes associated with bipolar I disorder in adult or pediatric patients and as an adjunctive treatment for major depressive disorder in adults, aripiprazole is also approved for the treatment of irritability associated with autism spectrum disorder and for the treatment of Tourette's disorder in children (Otsuka 2022). Brexpiprazole is approved for use in treating schizophrenia in adults and in pediatric patients (ages 13 years and older), use as an adjunct to antidepressant treatment in major depressive disorder in adults, and also use as monotherapy for the treatment of agitation associated with dementia due to Alzheimer's disease (Otsuka 2023).

Cariprazine acts as a partial agonist at D_3 and D_2 receptors with very high binding affinity and at serotonin type 1A ($5\text{-}HT_{1A}$) receptors with high binding affinity (see Table 34-1). It acts as an antagonist at serotonin type 2B ($5\text{-}HT_{2B}$) and type 2A ($5\text{-}HT_{2A}$) receptors with very high and moderate binding affinity, respectively, and at histamine type 1 (H_1) receptors with moderate binding affinity. Cariprazine shows weak binding affinity for serotonin type 2C ($5\text{-}HT_{2C}$) and type 7 receptors, very low affinity for a_{1A}-adrenergic receptors, and no appreciable affinity for cholinergic muscarinic receptors (Allergan 2022; Kiss *et al.* 2010). Postsynaptic D_2 receptor antagonism/partial agonism in the striatum is thought to be the principal means by which currently available antipsychotic medications decrease the intensity and frequency of the positive symptoms of schizophrenia (McCutcheon *et al.* 2019).

D_3 Receptors

Dopamine, the neurotransmitter primarily linked to psychosis, has very high affinity for D_3 receptors. D_3 autoreceptors, which are primarily located in the limbic system, control phasic (not tonic) activity of dopamine nerve cells and mediate behavioral abnormalities induced by glutamatergic *N*-methyl-D-aspartate receptor antagonists (Kiss *et al.* 2021).

The signaling pathways of D_3 receptors are distinct from those of other dopamine receptors (Kiss *et al.* 2021). Selective D_3 receptor antagonism has therapeutic effects in schizophrenia and beyond, as demonstrated by improved cognitive function, emotion processing, executive function, flexibility, and social behavior in preclinical studies. D_3 receptor antagonism seems to contribute to the atypicality of antipsychotics by reducing motor extrapyramidal side effects (EPS); has no direct influence on prolactin release; and does not cause anhedonia, weight gain, or metabolic dysfunction (Gross and Drescher 2012; Gyertyan *et al.* 2011).

5-HT_{1A} Receptors

Cariprazine has a high affinity for human 5-HT_{1A} receptors and acts as a partial agonist at these receptors. The effect of cariprazine depends on the serotonin concentration at the site. Cariprazine's 5-HT_{1A} receptor partial agonism may contribute to its antidepressant efficacy (Blier and Ward 2003; El Mansari *et al.* 2020) and to its beneficial effects on negative symptoms and cognitive dysfunction in schizophrenia (Bantick *et al.* 2001; Sumiyoshi and Higuchi 2013), as suggested by preclinical studies.

5-HT_{2B} Receptors

Cariprazine has very high binding affinity for human 5-HT_{2B} receptors (K_i = 0.58 nM). Activity at these receptors may modulate dopamine release in the nucleus accumbens (Auclair *et al.* 2010; Devroye *et al.* 2017). Cariprazine's antagonist activity at 5-HT_{2B} receptors may contribute to its postulated effects on mood and cognition, as observed in preclinical studies.

5-HT_{2A} Receptors

Cariprazine's binding affinity for human 5-HT_{2A} receptors is lower than that of aripiprazole and brexpiprazole. In theory, antagonist effects at 5-HT_{2A} receptors are essential for the atypicality of antipsychotics (Mocci *et al.* 2014). It is unknown whether cariprazine's relatively low affinity for 5-HT_{2A} receptors has any clinical implications.

H_1 Receptors

Cariprazine's moderate affinity for H_1 receptors is roughly equivalent to the affinity of aripiprazole and brexpiprazole for these receptors (Citrome 2015). Sedation and orthostatic hypotension with high dosages of cariprazine might be related to this property; however, clinical trials have demonstrated a very low rate of sedation-or somnolence-related adverse events (Citrome 2018).

PET

In a Phase I open-label study, patients with schizophrenia received multiple-dosage cariprazine treatment for 15 days (Girgis *et al.* 2016). A clear dose-occupancy relationship existed for acute, day 4/5, and subchronic treatment, with the highest occupancy for both D_2 and D_3 receptors observed with the highest dosage (12 mg/day). For dosages of 12 mg/day, 3 mg/day, and 1 mg/day, respectively, the mean D_3 receptor occupancies were 99%, 92%, and 76%, and the mean D_2 receptor occupancies were 95%, 79%, and 45%. After subchronic (15-day) administration, cariprazine showed a threefold greater preference for D_3 versus D_2 receptors. The increased D_3/D_2 selectivity after subchronic dosing compared with acute dosing may be related to the pharmacological activity of cariprazine's metabolites.

Pharmacokinetics

In a Phase I double-blind, placebo-controlled tolerance study, the pharmacokinetic properties of cariprazine were similar in healthy volunteers and patients with schizophrenia (Kapas *et al.* 2008). Furthermore, a compartmental analysis revealed that changes in pharmacokinetic properties by age, sex, or race/ethnicity were not large enough to require dose adjustments (Periclou *et al.* 2021).

In premarketing studies investigating cariprazine's tolerability in specific populations, patients with either mild or moderate hepatic impairment (Child-Pugh score 5-9), in comparison with healthy subjects, had approximately 25% higher exposure (peak serum concentration and area under the curve) to the parent drug, and approximately 45% lower exposure to the major active metabolites (DCAR and DDCAR), following a single daily dose of 1 mg cariprazine or 0.5 mg cariprazine for 14 days. Pharmacokinetic analyses in patients with renal impairment showed no significant relationship between plasma clearance and creatinine clearance (Allergan 2022).

Absorption and Distribution

Cariprazine can be taken with or without food. Food causes a slight delay but has no significant effect on the extent of absorption (Meszaros *et al.* 2007).

The effect of a meal on the pharmacokinetics of cariprazine was evaluated in an open-label randomized crossover study in 12 healthy male volunteers who received a single oral dose of 2 mg. Time to maximum concentration (T_{max}) was observed at 3-4 hours under fasting conditions.

Previous consumption of a meal delayed absorption of the drug but did not affect the final extent of absorption. The plasma profile of cariprazine followed a multi-exponential disposition, with a terminal half-life of 5-6 days (Meszaros *et al.* 2007).

Peak serum concentrations are reached between 3 and 6 hours. There is a linear relationship between dose and plasma concentration. Cariprazine and its major active metabolites are highly bound (91%-97%) to plasma proteins (Allergan 2022). Cariprazine and DCAR reach steady-state concentrations within 1-2 weeks (Figure 34-2); by contrast, DDCAR requires 4-8 weeks of daily cariprazine administration to reach steady-state levels.

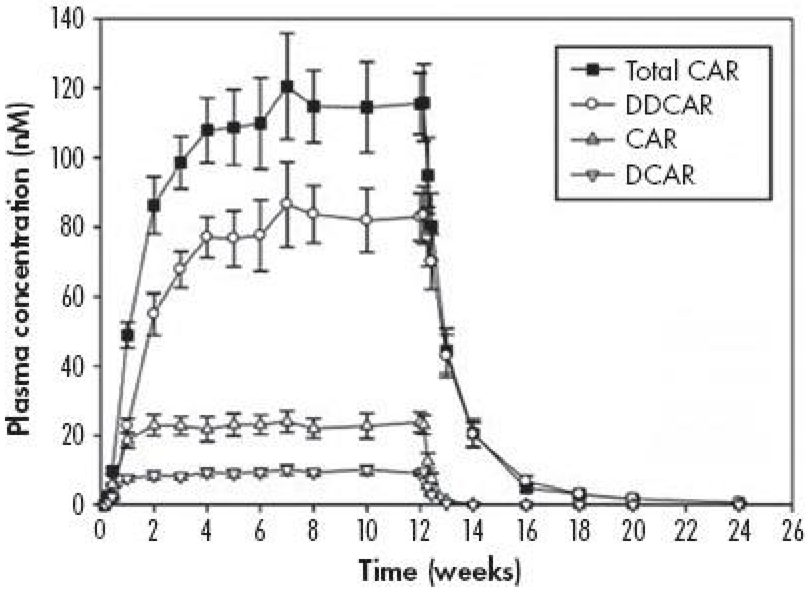

FIGURE 34-2. Plasma concentration at trough (mean +- SE) over time during and following 12 weeks of treatment with cariprazine 6 mg/day.

DDCAR is the predominant circulating moiety, representing about 70% of the total exposure. When treatment is discontinued, DDCAR concentrations persist longer than CAR or DCAR. CAR = cariprazine; DCAR = desmethyl-cariprazine; DDCAR = didesmethyl-cariprazine; total CAR = summed concentration of CAR, DCAR, and DDCAR.

Source. Adapted from Figure 1 (p. 30) in VRAYLAR(r) (cariprazine) full prescribing information. Revised 12/2022. Copyright (c) 2022 Allergan. All rights reserved. Available at: https://www.rxabbvie.com/pdf/vraylar_pi.pdf. Accessed July 7, 2023.

In a double-blind study of male patients with schizophrenia who were randomly assigned to cariprazine (0.5 mg/day increasing to 12.5 mg/day) or placebo, pharmacokinetic sampling was conducted for 37 days (Ereshefsky *et al.* 2008; Veselinovic *et al.* 2013). Systemic exposure to the metabolites DCAR and DDCAR was relatively low compared with exposure to the parent drug, cariprazine, on the first day of dosing (0.5 mg/day); however, on the last day of dosing (12.5 mg/day), systemic exposure to DDCAR was threefold greater than that to cariprazine for the plasma concentration area under the curve (AUC) over 24 hours and sixfold greater for the AUC over 7 days, indicating a slower elimination and a substantially longer half-life for DDCAR than for the parent compound. In a multicenter randomized, open-label, parallel-group 28-week study evaluating the pharmacokinetics of cariprazine and its two metabolites in 38 adult Japanese patients with schizophrenia, once-daily cariprazine at a fixed dosage (3, 6, or 9 mg/day) was administered. The effective half-life (calculated from time to steady state) of the total active moieties was approximately 1 week (Nakamura *et al.* 2016). Terminal half-lives of cariprazine, DCAR, and DDCAR ranged from 31.6 to 68.4 hours, 29.7 to 37.5 hours, and 314 to 446 hours, respectively.

According to a warning/precaution in cariprazine's product label, after cariprazine therapy is initiated or the dosage changed, response and side effects should be monitored for several weeks because of the long half-life of cariprazine's active metabolite DDCAR (Allergan 2022).

Metabolism and Elimination

Cariprazine is extensively metabolized by hydroxylation and demethylation in the liver cytochrome P450 (CYP) enzyme system, mainly by the 3A4 enzyme and to a lesser extent by the 2D6 enzyme. Eight metabolites for cariprazine were identified in liver microsomes (Kirschner *et al.* 2008), but only two active metabolites, DCAR and DDCAR, were clinically relevant (equipotent to cariprazine with similar receptor partial agonism [Kiss *et al.* 2019]; see also Figure 34-1).

Cariprazine's main metabolite, DCAR, is further metabolized by CYP3A4 and CYP2D6 to DDCAR, which is metabolized by CYP3A4 to a hydroxylated metabolite (Allergan 2022). In the Nakamura *et al.* (2016) study described above, cariprazine and DCAR levels had decreased by more than 90% 1 week after the last dose, whereas DDCAR levels had decreased by approximately 50% at 1 week; total active moieties had decreased by approximately 90% at 4 weeks. Cariprazine and its metabolites were eliminated almost completely in the 12 weeks following the last cariprazine dose (Nakamura *et al.* 2016).

Following administration of cariprazine 12.5 mg/day to patients with schizophrenia for 27 days, about 21% of the daily dose was found in urine, with approximately 1.2% of the daily dose excreted in urine as unchanged cariprazine (Allergan 2022).

Drug-Drug Interactions

Cariprazine and its major active metabolites are weak competitive inhibitors of the human CYP2D6 and CYP3A4 isozymes. They have no induction effect on the CYP enzyme system in human hepatocytes. Cariprazine is a weak inhibitor of several CYP isoenzymes in vitro: 1A2, 2C9, 2D6, 3A4, 2C19, 2A6, and 2E1 (Allergan 2022).

Because cariprazine is highly metabolized by CYP3A4 and metabolized to some degree by CYP2D6, changes in steady-state plasma concentrations would be expected if the drug were coadministered with potent CYP3A4 inhibitors or inducers. However, CYP2D6 inhibitors are not expected to significantly alter cariprazine metabolism, because CYP2D6 is known to be a relatively poor metabolizer of cariprazine and its metabolites, and CYP2D6 metabolizer status was not associated with any clinically relevant change in a population pharmacokinetic study (Periclou *et al.* 2021).

Taking a strong CYP3A4 inhibitor (e.g., ketoconazole) with cariprazine will increase concentrations of the parent drug by about 3.5-fold, decrease DCAR by about one-third, and increase DDCAR by about 1.5-fold. The concomitant use of CYP3A4 inducers with cariprazine has not yet been evaluated. When cariprazine is to be added to an existing regimen of a strong CYP3A4 inhibitor, the recommended starting dosage is 1.5 mg every other day, with a maximum dosage of 3 mg/day (Allergan 2022).

Indications, Dosing, and Efficacy

Cariprazine's half-life of more than 24 hours allows once-daily dosing, which is an advantage in terms of antipsychotic adherence. The cariprazine starting dosage is 1.5 mg/day for all indications. The recommended dosage is 1.5-6 mg/day for patients with schizophrenia, 3-6 mg/day for patients with bipolar mania, and 1.5 mg/day or 3 mg/day for patients with bipolar depression or for adjunctive use in major depressive disorder. Any dosage changes will be reflected fully in the serum level 2 weeks after initial dosing. In short-term controlled trials, dosages above 6 mg/day did not confer increased effectiveness sufficient to outweigh dosage-related adverse reactions (Allergan 2022).

FDA-Approved Indications

Acute Treatment of Schizophrenia

For the treatment of patients with schizophrenia, the recommended dosage of cariprazine is 1.5-6 mg/day. The recommended starting dosage of 1.5 mg/day can be increased to 3 mg/day on day 2, with further upward dosage increments of 1.5 mg/day or 3 mg/day as necessary, depending on clinical response and tolerability (Allergan 2022).

FDA approval for treating schizophrenia was based on data from three positive 6-week double-blind, randomized, placebo-controlled studies of cariprazine that were conducted in adult patients with schizophrenia between 2008 and 2011. Two of the studies used fixed dosages and included active drug controls (risperidone and aripiprazole) (Allergan 2022). All three trials consisted of a washout period of up to 1 week, 6 weeks of double-blind treatment, and a 2-week safety follow-up. The primary efficacy measure in each study was change from baseline in the Positive and Negative Syndrome Scale (PANSS) total score; assessments were conducted at screening, at baseline, and at the end of each double-blind treatment week (weeks 1-6) (Table 34-2).

(Kane *et al.* 2015)	Cariprazine flexible dosing: 3-6 mg/day (151) 6-9 mg/day (148)		
	No active control group		

Note. CGI-S = Clinical Global Impression-Severity; LOCF = last observation carried forward; LSMD = least squares mean differences; PANSS = Positive and Negative Syndrome Scale.

[a] Trial registration: ClinicalTrials.gov identifiers NCT00694707, NCT01104766, and NCT01104779.

[b] In each study, the PANSS was used as the primary measure and the CGI-S rating scale was used as the secondary efficacy measure. The primary endpoint was change from baseline in PANSS total score at the end of week 6. The change from baseline for cariprazine and for all active control groups was superior to placebo in all three trials.

[c] The active control medications (aripiprazole and risperidone) were included for use in assessment of assay sensitivity and not for efficacy comparisons. However, they were superior to placebo.

As indicated in Table 34-2, patients were randomly assigned to receive cariprazine (1.5 mg/day, 3 mg/day, or 4.5 mg/day), risperidone (4 mg/day), or placebo in the NCT00694707 study; cariprazine (3 mg/day or 6 mg/day), aripiprazole (10 mg/day), or placebo in the NCT01104766 study; and cariprazine (3-6 mg/day or 6-9 mg/day) or placebo in the NCT01104779 study. The greater efficacy of cariprazine compared with placebo was demonstrated at dosages ranging from 1.5 mg/day to 9 mg/day. There was, however, a dosage-related increase in certain adverse effects (e.g., acute EPS), particularly at dosages above 6 mg/day (Kane *et al.* 2015). Findings regarding the time course of efficacy in the NCT01104766 study are shown in Figure 34-3 (Allergan 2022).

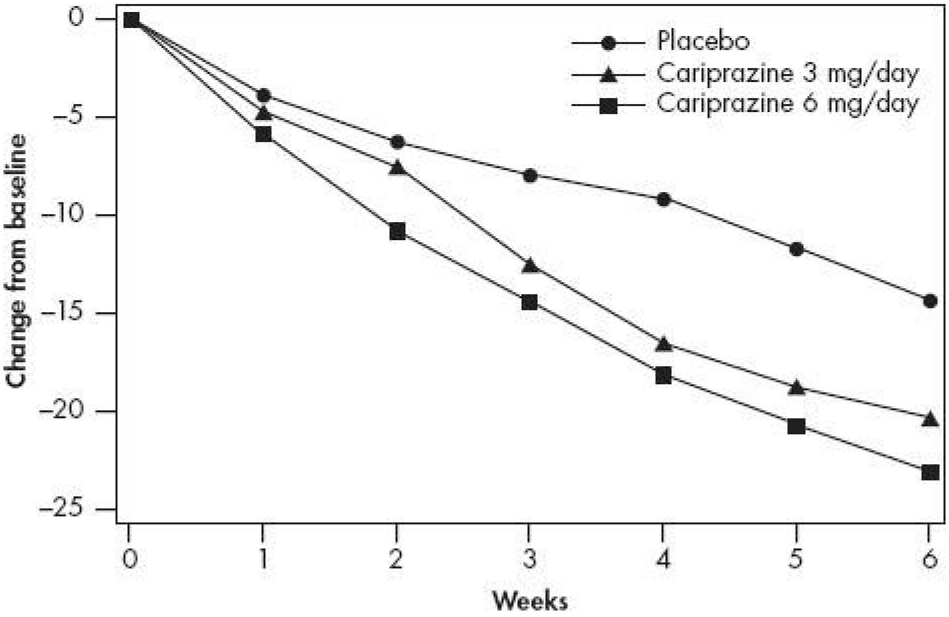

FIGURE 34-3. Change from baseline in Positive and Negative Syndrome Scale total score by weekly visit (ClinicalTrials.gov identifier: NCT01104766).

Source. Adapted from Figure 2 (p. 36) in VRAYLAR(r) (cariprazine) full prescribing information. Revised 12/2022. Copyright (c) 2022 Allergan. All rights reserved. Available at: https://www.rxabbvie.com/pdf/vraylar_pi.pdf. Accessed July 7, 2023.

In the Phase III clinical trials, dosages of 3-9 mg/day produced significant improvement on the PANSS and on the Clinical Global Impression Scale. Higher dosages (6-9 mg/day) showed early separation from placebo (by the end of week 1) but carried a dosage-related risk of adverse events (Kane *et al.* 2015), which led the FDA to recommend 6 mg/day as the maximum dosage (Citrome 2018).

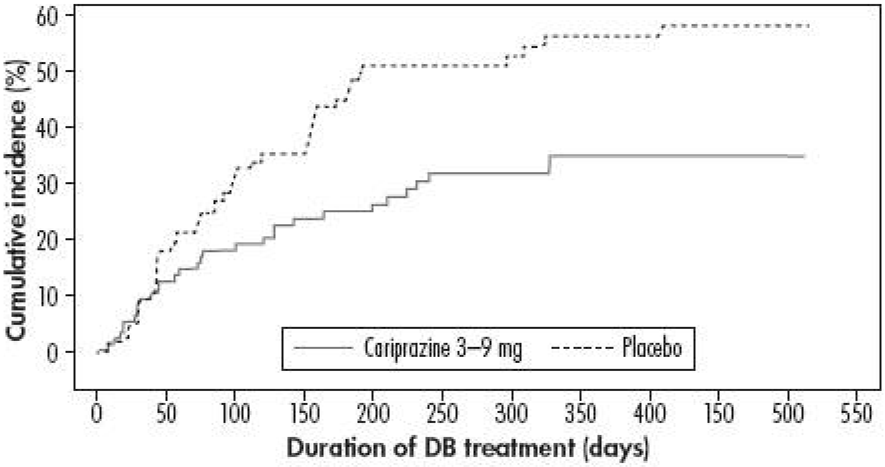
The effects of cariprazine on human cognition were evaluated in the NCT01104779 study (at weeks 0, 3, and 6). No significant differences were observed for the cariprazine group versus the placebo group on the

Cognitive Drug Research System Attention Battery Tests or the Color Trails Test (Kane *et al.* 2015).

An earlier Phase II 6-week double-blind, placebo-controlled proof-of-concept study (NCT00404573) evaluated the efficacy, safety, and tolerability of low-dosage (1.5-4.5 mg/day) versus high-dosage (6-12 mg/day) cariprazine in patients with schizophrenia. No significant differences between the two dosages of cariprazine and placebo were noted on PANSS total score changes or any other efficacy variables (Clinical Global Impression--Severity scale or PANSS subscales) after adjustment for multiplicity (Durgam *et al.* 2016d).

Maintenance Treatment of Schizophrenia

A supplemental new drug application for cariprazine for the maintenance treatment of adults with schizophrenia was approved by the FDA in November 2017 (U.S. Food and Drug Administration 2017) on the basis of a placebo-controlled, randomized withdrawal study in nonelderly adult patients with schizophrenia (Durgam *et al.* 2016b; Earley *et al.* 2018a). To participate in the trial, patients were required to be acutely ill at screening. During the 20-week open-label treatment phase, patients received cariprazine 3-9 mg/day (starting at 1.5 mg/day on day 1 and increasing to 3 mg/day on day 2); for patients with inadequate response and no significant tolerability issues, dosage increases were allowed on day 6 (6 mg/day [interim increase to 4.5 mg/day on day 4]) and day 10 (9 mg/day) if needed. Dosage decreases to 3 mg/day or 6 mg/day were allowed for patients with significant tolerability issues. To be eligible for random selection to either continue cariprazine or receive placebo, patients needed to meet prespecified stability criteria. Patients were required to be hospitalized during screening and for the first 2 weeks of the run-in phase. The double-blind, randomized phase consisted of 26-72 weeks of fixed-dose treatment at the same dosage as in the stabilization phase. The primary efficacy outcome was time to first relapse, defined by worsening of symptom scores, psychiatric hospitalization, aggressive/violent behavior, or risk for suicide. A total of 264 of 765 patients (34.5%) completed the open-label phase, and 200 patients were randomly assigned to a group. Demographic and baseline characteristics of the participants entering the open-label phase were like those for the acute short-term trials described earlier. The baseline PANSS score at the start of the double-blind phase was 51. About 50% of all cariprazine patients received 9 mg/day at randomization, 37% received 6 mg/day, and 14% received 3 mg/day. According to Kaplan-Meier analysis, time to relapse was significantly longer for patients who continued cariprazine than for patients randomly selected to receive placebo (hazard ratio 0.45, 95% CI 0.28-0.73). A sensitivity analysis conducted in response to an FDA request (Earley *et al.* 2018a) resulted in a hazard ratio of 0.52 (95% CI 0.33-0.82), as shown in the product label (Allergan 2022). Of note, between-group separation between cariprazine and placebo did not occur until around day 50 (Figure 34-4), possibly because of the long half-life of cariprazine (and specifically DDCAR) (Correll *et al.* 2019).



At Risk	Cariprazine 3–9 mg	101	81	72	64	54	48	44	38	32	26	18	0
	Placebo	99	75	58	54	38	32	28	23	23	21	16	0
Event	Cariprazine 3–9 mg	0	12	18	22	24	28	28	30	30	30	30	30
	Placebo	0	17	30	32	45	45	46	48	48	49	49	49

FIGURE 34-4. Kaplan-Meier curves of cumulative rate of relapse during double-blind (DB) treatment.

Although this study permitted dosing of cariprazine at 3-9 mg/day, the maximum recommended daily dosage was 6 mg. Between-group separation of the curves did not occur until around day 50, possibly because of the long half-life of cariprazine (and specifically didesmethyl-cariprazine [DDCAR]) lending some extended protection against the risk of relapse.

Source. Adapted from Figure 3 (p. 37) in VRAYLAR(r) (cariprazine) full prescribing information. Revised 12/2022. Copyright (c) 2022 Allergan. All rights reserved. Available at: https://www.rxabbvie.com/pdf/vraylar_pi.pdf. Accessed July 7, 2023.

Additional Study for Negative Symptoms in Schizophrenia

Cariprazine's European summary of product characteristics (European Medicines Agency 2023) includes support for its efficacy for treating predominantly negative symptoms in patients with schizophrenia based on a 26-week double-blind, randomized study that compared cariprazine 4.5 mg/day with risperidone 4 mg/day in 460 nonelderly adult patients (Nemeth *et al.* 2017). There was no placebo control. In this study, patients were required to have a PANSS negative factor score of at least 24, with single-item scores of at least 4 (moderate) on selected symptoms, such as blunted affect, passive/apathetic social withdrawal, and lack of spontaneity and flow of conversation. Excluded were patients with a hospital admission or an acute exacerbation of schizophrenia within the 6 months prior to the study, a PANSS positive factor score greater than 19, significant fluctuations in positive or negative symptoms during the prospective lead-in period, treatment with clozapine in the 12 months prior to the study, moderate to severe depressive symptoms, clinically relevant parkinsonian symptoms, or treatment with antidepressant medications and/or anticholinergic medications (for abnormal movements). From randomization (day 0) to day 6, patients received cariprazine 1.5 mg/day or risperidone 2 mg/day. On days 7-13, patients received 3 mg/day of their respective study drug, and on day 14, patients received the target dosage of cariprazine 4.5 mg/day or risperidone 4 mg/day. Antipsychotic medication taken during the lead-in period was downtitrated during this period and discontinued on day 14. The dosage of the double-blind study medication could be decreased to 3 mg/day in the event of poor tolerability. In cases of impending psychotic deterioration, the dosage could be increased to 6 mg/day.

The subjects' mean age was 40 years, and 57% of patients were male. Overall, 77% of patients completed the double-blind treatment. The mean daily dosage was 4.2 mg for cariprazine and 3.8 mg for risperidone. Cariprazine was superior to risperidone on both the primary (PANSS negative factor score) and key secondary (Personal and Social Performance Scale) outcomes, with a modest effect size. For outcome variables analyzed to assess pseudospecific effects (change from baseline in PANSS positive symptoms, depression, and parkinsonian symptoms), changes were small and similar for cariprazine and risperidone. These results thus excluded indirect effects related to positive, depressive, or EPS improvement as a factor in improvement in negative symptoms. The most common adverse event for cariprazine was akathisia (8%), which was also observed in 5% of persons randomly selected to receive risperidone.

The study awaits replication. It has generated robust debate regarding the limitations of current approaches to the treatment of negative symptoms of schizophrenia (Kantrowitz 2021, 2022; Nemeth *et al.* 2022).

Acute Manic or Mixed Episodes Associated With Bipolar I Disorder

Cariprazine's efficacy in the treatment of bipolar manic or mixed episodes was established at dosages ranging from 3 mg/day to 12 mg/day. Dosages higher than 6 mg/day did not appear to add additional benefit over lower dosages, and there was a dosage-related increase in certain adverse effects (e.g., acute EPS). Therefore, the maximum recommended dosage is 6 mg/day. Findings on the time course of efficacy in the NCT01058668 study are shown in Figure 34-5 (Allergan 2022).

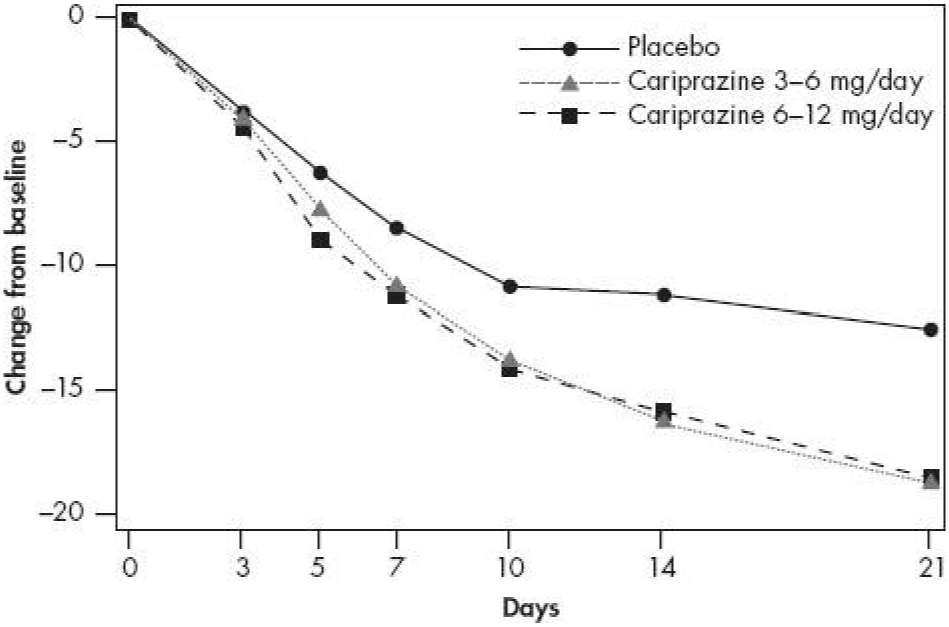


FIGURE 34-5. Change from baseline in Young Mania Rating Scale total score by study visit (ClinicalTrials.gov identifier: NCT01058668).

FDA approval for the bipolar disorder indication was based on data from three 3-week placebo-controlled trials in adults with manic or mixed episodes of bipolar I disorder with or without psychotic features. All three studies demonstrated cariprazine's superiority over placebo (Table 34-3).

TABLE 34-3. Three 3-week randomized, placebo-controlled, flexibly dosed trials establishing the efficacy of cariprazine in acute manic/mixed episodes of bipolar I disorder

Trial[a]	Randomization (*N*)	Efficacy[b]	Side effects

Trial[a]	**Randomization (*N*)**	**Efficacy**[b]	**Side effects**
NCT01058668	Total *N*: 497	At week 3, statistically significant LSMD in favor of cariprazine versus placebo were observed for	The most common ([?] 5%; twice the rate of placebo) treatment-related adverse events for cariprazine were akathisia (both groups) and nausea, constipation, and tremor (6-12 mg/day only).
Phase III	74% completed the study	* YMRS-Total (3-6 mg/day: [?] 6.1; 6-12 mg/day: [?] 5.9; *P* < 0.001 [both]).	There were no statistically significant differences between cariprazine and placebo in mean change from baseline in metabolic variables, liver enzymes, or prolactin, with the exception of increased triglycerides in the 3-6 mg/day group.
(Calabrese *et al.* 2015)	Cariprazine flexible dosing: 3-6 mg/day (167) 6-9 mg/day (169) Placebo (161)	* CGI-S (3-6 mg/day: [?] 0.6; 6-12 mg/day: [?] 0.6; *P* < 0.001 [both]).	

Trial[a]	**Randomization (*N*)**	**Efficacy**[b]	**Side effects**
NCT00488618	Total *N*: 238	At week 3, statistically significant LSMD in favor of cariprazine versus placebo were observed for	The most common adverse events (> 10% for cariprazine) were extrapyramidal disorder, headache, akathisia, constipation, nausea, and dyspepsia.
Phase II	63% completed the study	* YMRS-Total (3-12 mg/day: [?] 6.1; $P < 0.001$).	Changes in metabolic variables were similar between groups, with the exception of fasting glucose change.
(Durgam *et al.* 2015b)	Cariprazine flexible dosing: 3-12 mg/day (118) Placebo (120)	* CGI-S (3-12 mg/day: [?] 0.6; $P < 0.001$).	
NCT01058096	Total *N*: 312	At week 3, statistically significant LSMD in favor of cariprazine versus placebo were observed for	The most common cariprazine-related (> 10%; twice the rate of placebo) treatment-emergent adverse events were akathisia, extrapyramidal disorder, tremor, dyspepsia, and vomiting.

Trial[a]	**Randomization (*N*)**	**Efficacy**[b]	**Side effects**
Phase III	69% completed the study	* YMRS-Total (3-12 mg/day: [?] 4.3; *P* = 0.0004).	Mean changes from baseline in metabolic variables were generally small and similar between groups.
(Sachs *et al.* 2015)	Cariprazine flexible dosing: 3-12 mg/day (158) Placebo (154)	* CGI-S (3-12 mg/day: [?] 0.4; *P* = 0.0027).	

Note. CGI-S = Clinical Global Impression-Severity; LSMD = least squares mean differences; YMRS-Total = Young Mania Rating Scale total score.

[a] Trial registration: ClinicalTrials.gov identifiers NCT01058668, NCT00488618, and NCT01058096.

[b] In all trials, patients were adults (ages 18-65 years; mean age = 39 years) whose symptoms met DSM-IV-TR criteria for bipolar I disorder with manic or mixed episodes and with or without psychotic features (YMRS score [?] 20). YMRS and CGI-S were used as the primary and secondary efficacy measures, respectively; the primary endpoint was decrease from baseline in YMRS-Total score at the end of week 3. The change from baseline for cariprazine was superior to placebo in all three trials. All three trials lacked an active control arm and had a short duration.

Bipolar Depression

Cariprazine monotherapy received approval by the FDA in 2019 for the treatment of depressive episodes associated with bipolar I disorder (bipolar depression) (U.S. Food and Drug Administration 2019). The efficacy of cariprazine for this indication was established in one 8-week (Durgam *et al.* 2016c) and two 6-week (Earley *et al.* 2019, 2020a) fixed-dose placebo-controlled trials in patients (mean age 41.6 years, range 18-65 years) whose symptoms met DSM-IV-TR (American Psychiatric Association 2000) or DSM-5 (American Psychiatric Association 2013) criteria for depressive episodes associated with bipolar I disorder (Table 34-4). In each study, the primary endpoint was change from baseline in the Montgomery-Asberg Depression Rating Scale (MADRS) total score at the end of week 6

(Allergan 2022). In each study, the cariprazine 1.5 mg/day dosage demonstrated statistical significance over placebo, but the same was not true for cariprazine 3 mg/day (Citrome 2019). Findings on the time course of efficacy in the NCT02670551 study are shown in Figure 34-6 (Allergan 2022). An earlier study that had tested flexible dosing of cariprazine in two ranges (0.25-0.75 mg/day and 1.5-3 mg/day) failed to demonstrate statistical separation from placebo (Yatham *et al.* 2020).

Adjunctive Use in Major Depressive Disorder

Cariprazine received FDA approval in 2022 for use as adjunctive therapy to antidepressants in the treatment of major depressive disorder in adults (U.S. Food and Drug Administration 2022). The efficacy of cariprazine for this indication was established in an 8-week (Durgam *et al.* 2016a) and a 6-week (Sachs *et al.* 2023) placebo-controlled trial in patients (mean age 45 years, range 18-65 years) whose symptoms met DSM-IV-TR (American Psychiatric Association 2000) or DSM-5 (American Psychiatric Association 2013) criteria for major depressive disorder (with or without symptoms of anxiety) and who had experienced an inadequate response to 1 to 3 courses of prior antidepressant therapy. Inadequate response during antidepressant treatment was defined as less than 50% improvement to antidepressant treatment of adequate dosage and duration (Table 34-5). In each study, the primary endpoint was change from baseline in the MADRS total score at study endpoint (Allergan 2022). Statistically significant differences versus placebo for 2-4.5 mg/day but not 1-2 mg/day was found in one study (Durgam *et al.* 2016a), and statistically significant differences from placebo for adjunctive cariprazine 1.5 mg/day but not 3 mg/day was found in the other (Sachs *et al.* 2023). No statistically significant differences versus placebo were found for adjunctive cariprazine 0.1-0.3 mg/day or 1-2 mg/day in another study (Fava *et al.* 2018), and no statistically significant differences for cariprazine 1.5-4.5 mg/day versus placebo were observed in a fourth published study (Earley *et al.* 2018b). Lastly, an additional Phase III study was completed that did not demonstrate statistically significant differences from placebo for either 1.5 mg/day or 3 mg/day (Riesenberg *et al.* 2023). Findings on the time course of efficacy in the NCT03738215 study (Sachs *et al.* 2023) are shown in Figure 34-7 (Allergan 2022).

TABLE 34-5. One 8-week and one 6-week randomized, placebo-controlled trial establishing the efficacy of adjunctive cariprazine in treating major depressive disorder

Trial[a]	**Randomization (*N*)**	**Efficacy**[b]	**Side effects**
NCT01469377	Total *N*: 819	At week 8, statistically significant LSMD in favor of cariprazine vs. placebo were observed for	The most common ([?] 5%; twice the rate of placebo) treatment-related adverse events for cariprazine was akathisia (both groups), insomnia (2-4.5 mg/day), nausea (2-4.5 mg/day), restlessness (both groups), somnolence (2-4.5 mg/day), fatigue (2-4.5 mg/day), tremor (2-4.5 mg/day), dizziness (2-4.5

Trial[a]	**Randomization (*N*)**	**Efficacy**[b]	**Side effects**
			mg/day), constipation (2-4.5 mg/day), and increased appetite (2-4.5 mg/day.
Phase II	82% completed the study	* MADRS-Total (2-4.5 mg/day: [?] 2.2; $P = 0.0114$); result was not statistically significant for cariprazine 1-2 mg/day vs. placebo.	Rates of weight gain were generally low and descriptively similar for placebo and cariprazine.
(Durgam *et al.* 2016a)	Cariprazine flexible dosing: 1-2 mg/day (274) 2-4.5 mg/day (276) Placebo (269)		
NCT03738215	Total N: 759	At week 6, statistically significant LSMD in favor of cariprazine vs. placebo were observed for	The most common ([?] 5%; twice the rate of placebo) treatment-related adverse events for cariprazine were akathisia (both groups) and nausea (both groups).

Trial[a]	**Randomization (*N*)**	**Efficacy**[b]	**Side effects**
Phase III	89% completed the study	* MADRS-Total (1.5 mg/day: [?] 2.5; *P* = 0.0025); result was not statistically significant for cariprazine 3 mg/day vs. placebo.	Cariprazine at both dosages resulted in non-clinically significant metabolic changes and weight gain.
(Sachs *et al.* 2023)	Cariprazine flexible dosing: 1.5 mg/day (252) 3 mg/day (253) Placebo (254)		

Note. LSMD = least squares mean differences using a mixed-effects model for repeated measures; MADRS-Total = Montgomery-Asberg Depression Rating Scale total.

[a] Trial registration: ClinicalTrials.gov identifiers NCT01469377 and NCT02670538.

[b] In all trials, patients were adults (ages 18-65 years; mean age 45 years) whose symptoms met DSM-IV-TR (American Psychiatric Association 2000) or DSM-5 (American Psychiatric Association 2013) criteria for major depressive disorder, with or without symptoms of anxiety and who had an inadequate response to 1 to 3 courses of prior antidepressant therapy. Inadequate response during antidepressant treatment was defined as less than 50% improvement to antidepressant treatment of adequate dosage and duration. MADRS was used as the primary efficacy measure; the primary endpoint was decrease from baseline in the MADRS-Total score at the end of week 8 (NCT01469377) or week 6 (NCT03738215). Both trials lacked an active control arm and were of short duration.

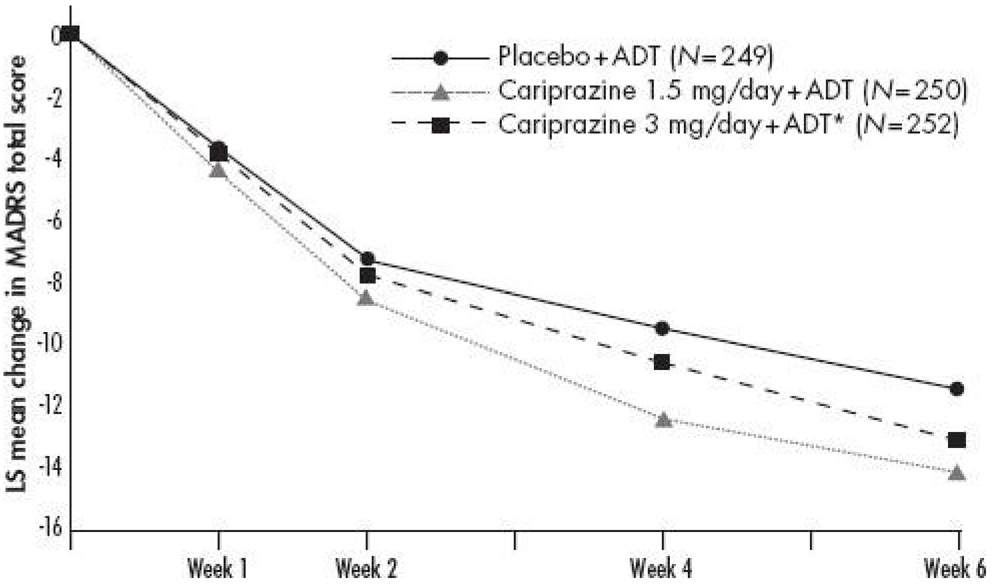

FIGURE 34-7. Least squares (LS) mean change from baseline in Montgomery-Asberg Depression Rating Scale (MADRS) total score by study visit (ClinicalTrials.gov identifier: NCT03738215).

ADT = antidepressant.

* Dosage was not clinically significant.

Source. Adapted from Figure 6 (p. 43) in VRAYLAR(r) (cariprazine) full prescribing information. Revised 12/2022. Copyright (c) 2022 Allergan. All rights reserved. Available at: https://www.rxabbvie.com/pdf/vraylar_pi.pdf. Accessed July 7, 2023.

In a pooled analysis of data from all five acute randomized, placebo-controlled clinical trials of adjunctive cariprazine in adults with major depressive disorder, cariprazine at dosages greater than or equal to 1 mg/day evidenced a statistically significant benefit on the categorical outcome of response (as measured by a 50% or greater decrease from baseline on the MADRS total score), with a dose-response relationship favoring better tolerability for the lower dosage range (1-2 mg/day or 1.5 mg/day) (Citrome et al 2023). Also supporting the indication for major depressive disorder was a Phase III multicenter long-term (26-week), flexible-dosage (1.5-4.5 mg/day) open-label safety study (Vieta *et al.* 2019) in which the mean change from the open-label baseline in the MADRS total score at week 26 was -7.3. By week 26, 53.3% of patients were in remission (defined as a MADRS total score [?] 10).

Side Effects and Toxicology

Cariprazine was generally well tolerated in the short-term trials for schizophrenia, bipolar I mania, bipolar I depression, and adjunctive use in major depressive disorder. No significant anticholinergic or antiadrenergic treatment-emergent adverse events (TEAEs) were documented, because cariprazine has negligible affinity for cholinergic and adrenergic receptors (Allergan 2022).

Atypical Antipsychotic Class Warnings

Numerous risks are associated with the use of atypical antipsychotic medications in general. As a member of this class, and because of its antidepressant indication, cariprazine carries the following warnings and precautions (Allergan 2022):

1. Increased mortality in elderly patients with dementia-related psychosis
2. Suicidal thoughts and behaviors in children, adolescents, and young adults
3. Cerebrovascular adverse reactions, including stroke, in elderly patients with dementia-related psychosis
4. Neuroleptic malignant syndrome
5. Tardive dyskinesia
6. Metabolic changes
7. Leukopenia, neutropenia, and agranulocytosis
8. Orthostatic hypotension and syncope
9. Falls
10. Seizures

11. Potential for cognitive and motor impairment
12. Body temperature dysregulation
13. Dysphagia

These warnings are based on the pharmacological actions of this class (Citrome and Nasrallah 2012). In the front section of the product label containing "Highlights of Prescribing Information," the most common adverse reactions--defined as an incidence of at least 5% and at least twice the rate of placebo--are listed by approved indication (Allergan 2022). For schizophrenia, the most common adverse reactions are EPS and akathisia; for bipolar mania, EPS, akathisia, dyspepsia, vomiting, somnolence, and restlessness; for bipolar depression, nausea, akathisia, restlessness, and EPS; and for adjunctive treatment of major depressive disorder, akathisia, restlessness, fatigue, constipation, nausea, insomnia, increased appetite, dizziness, and EPS. Differences in rates of some adverse events (e.g., akathisia) have emerged because of study design variations in details including dosage, titration, and study duration.

Late-Occurring Adverse Drug Reactions

Cariprazine has a long half-life, but the half-life of its major metabolite, DDCAR, is even longer. Therefore, plasma levels accumulate over time, and side effects may appear weeks after the initiation of treatment. As a result, the incidence of adverse reactions in short-term trials may not reflect the rates after longer-term exposure. Clinicians are advised to monitor for adverse reactions for several weeks after a patient begins taking cariprazine and after any dosage increase. If side effects are noted, dosage reduction or medication discontinuation should be considered (Allergan 2022).

Akathisia and Acute Extrapyramidal Symptoms

In a post hoc analysis that evaluated the safety and tolerability of cariprazine in the acute treatment of schizophrenia, data from four 6-week randomized, double-blind, placebo-controlled trials of cariprazine were used to examine modal daily dosage subgroups of cariprazine 1.5-3 mg/day, 4.5-6 mg/day, and 9-12 mg/day (Earley *et al.* 2017a). A dose-response relationship was observed for akathisia and EPS. Most events of akathisia and EPS were considered mild or moderate in severity. Rates of discontinuation for EPS, akathisia, and restlessness were less than or equal to 2% among cariprazine-treated patients. During double-blind treatment, the mean duration of akathisia was 24 days for cariprazine-treated patients and 29 days for placebo-treated patients. The onset of akathisia generally occurred within 2-3 weeks of the initiation of cariprazine treatment.

In a post hoc analysis that evaluated the safety and tolerability of cariprazine in the treatment of bipolar mania, data were taken from three 3-week randomized, double-blind, placebo-controlled, flexible-dosage trials of cariprazine 3-12 mg/day (Earley *et al.* 2017b). The incidence of treatment-emergent akathisia and parkinsonism was higher in both cariprazine groups (3-6 mg/day and 9-12 mg/day) than in the placebo group. Most incidents of EPS-related TEAEs in both cariprazine groups were considered to be mild or moderate, and EPS-related TEAEs rarely led to study discontinuation. Akathisia and EPS onset peaked approximately 2 weeks after the start of treatment for both placebo-and cariprazine-treated patients; the mean duration of akathisia was 15 days and 14 days in the placebo and cariprazine groups, respectively. When examined by modal daily dosage, the data revealed a dose-response relationship for cariprazine for the TEAE of EPS.

A post hoc analysis was done for patients with bipolar depression and focused specifically on akathisia, restlessness, and EPS (Citrome *et al.* 2021). Among participants

in the three fixed-dosage, 6-or 8-week clinical studies of cariprazine 1.5 mg/day and 3 mg/day in bipolar depression, the incidence of akathisia was 7.6% for cariprazine overall (1.5 mg/day, 5.5%; 3 mg/day, 9.6%) and 2.1% for placebo; acute EPS occurred in 4.5% of cariprazine-treated patients (1.5 mg/day, 3.8%; 3 mg/day, 5.1%) and 2.1% of placebo-treated patients. Most TEAEs were mild/moderate, occurred during the first 3 weeks of cariprazine initiation or dose increase, and resulted in few discontinuations (< 3%); median time to resolution of an akathisia or EPS TEAE after the last dose of cariprazine was approximately 1 week. Rescue medication was used by fewer than 3% of patients to manage akathisia/EPS events. Citrome and colleagues concluded that cariprazine-related akathisia and EPS can be minimized with conservative dosing and titration strategies.

Changes in Metabolic and/or Clinical Laboratory Variables

In the previously described pooled post hoc analysis of tolerability of cariprazine in the acute treatment of schizophrenia (Earley *et al.* 2017a) over 6 weeks, cariprazine-treated patients showed a decrease in mean total cholesterol, fasting low-density lipoprotein cholesterol, and triglyceride levels, whereas placebo-treated patients showed increases from baseline in these variables. The decrease in high-density lipoprotein cholesterol was similar for cariprazine and placebo, as was the increase in mean fasting blood glucose. Clinically relevant shifts in lipid and glucose variables were similar for cariprazine and placebo. The percentage of patients with an increase in fasting glucose of 10 mg/dL or greater was higher in the cariprazine group than in the placebo group; however, no clear dose-response relationship was observed. A weight increase of at least 7% was observed in 9.2% of cariprazine-treated patients and 4.7% of placebo-treated patients. Both mean weight change and shifts in weight of at least 7% were larger in the 9-12 mg/day dosage group, a dosage range that is not approved for use. Within the recommended cariprazine dosage range (1.5-6 mg/day), mean weight gain was 0.8-1.0 kg for cariprazine; the proportions of patients with a weight increase of at least 7% were 7.6% and 7.7% for the 1.5-3 mg/day and the 4.5-6 mg/day groups, respectively. There was no increase in prolactin level or in the incidence of electrocardiogram QTc interval greater than 500 milliseconds.

In the previously mentioned pooled post hoc analysis of tolerability of cariprazine in the acute treatment of bipolar mania (Earley *et al.* 2017b), changes in metabolic variables were small and were generally similar between cariprazine and placebo groups; mean increases in fasting glucose levels were greater with cariprazine (3-6 mg/day, 6.6 mg/dL; 9-12 mg/day, 7.2 mg/dL) than with placebo (1.7 mg/dL). Mean weight changes were 0.54 kg and 0.17 kg for cariprazine and placebo, respectively; fewer than 3% of all patients experienced a weight increase of at least 7%. Mean prolactin levels decreased in all treatment groups. Cariprazine was not associated with clinically meaningful changes in electrocardiographic variables; three patients had a corrected QT interval by Bazett (QTcB) greater than 500 milliseconds (two in the placebo group and one in the cariprazine 9-12 mg/day group).

In a pooled post hoc analysis of tolerability of cariprazine in the acute treatment of bipolar depression (Earley *et al.* 2020b), mean weight gain was less than 1 kg for cariprazine-treated patients; a body weight increase of at least 7% was observed in fewer than 4% of patients in each cariprazine modal dosage group. Metabolic changes were small and were generally similar for cariprazine and placebo; mean increase in glucose

was 3.1 mg/dL for cariprazine and 2.6 mg/dL for placebo. Fixed-dosage and modal dosage findings were generally consistent; values for most metabolic variables were slightly higher for a fixed dosage of 3 mg/day than 1.5 mg/day. Regarding prolactin levels, cariprazine-treated patients had a slight mean increase, and placebo-treated patients had a slight decrease. Mean changes in electrocardiographic variables were small and were similar for cariprazine and placebo; one patient in the cariprazine 1.5 mg/day modal dosage group had a corrected QT interval by Fredericia (QTcF) greater than 500 milliseconds.

Longer-Term Open-Label Clinical Trials

12-Week Open-Label Study in Schizophrenia

In a 12-week open-label, fixed-dosage (3 mg/day, 6 mg/day, or 9 mg/day) study of 38 adult patients with schizophrenia (Nakamura *et al.* 2016) conducted in Japan, the overall completion rate was 63.2%; 15.8% of patients discontinued the medication because of adverse events. No abnormal laboratory values or major differences from baseline in EPS were observed. A total of 37 (97.4%) patients reported at least one TEAE, and 31 (81.6%) patients experienced at least one adverse drug reaction (defined as an adverse event for which a causal relationship with cariprazine was determined to be "reasonably possible" [Nakamura *et al.* 2016, p. 334]). Side effects observed in this study were similar to those reported in previous studies. Across all dosage groups, akathisia was observed in 21% of patients during cariprazine treatment. One case of cataract (deemed mild in severity) was reported.

20-Week Open-Label Treatment Phase From the Schizophrenia Maintenance Study

The most commonly observed adverse events during the open-label phase of the schizophrenia maintenance study (Durgam *et al.* 2016b; Earley *et al.* 2018a) were akathisia (19%), insomnia (14%), and headache (12%). Akathisia and other EPS adverse events (excluding akathisia or restlessness) each led to discontinuation in approximately 1% of patients in the open-label treatment phase, whereas no EPS-related adverse events led to discontinuation during double-blind treatment. Weight gain of at least 7% was reported in 11% of open-label patients and in 32% of placebo-treated patients and 27% of cariprazine-treated patients during double-blind treatment. Changes from baseline in lipid variables at the end of open-label and double-blind treatment were generally not clinically relevant. There were no clinically relevant mean changes in blood pressure, and no patients had an electrocardiogram QTc interval greater than 500 milliseconds.

48-Week Open-Label Studies in Schizophrenia

A report that pooled data from two 48-week studies ($N = 679$) of open-label, flexible-dosage cariprazine in adult patients with schizophrenia (NCT01104792, 3-9 mg/day; NCT00839852, 1.5-4.5 mg/day) reported an overall completion rate of 40.1% (Nasrallah *et al.* 2017). The overall mean daily dosage of cariprazine was 5.42 mg. The mean duration of treatment with cariprazine (days +- SD) was 188.4 +- 136.8. The individual study reports for each of these 48-week studies have also been published (Cutler *et al.* 2018; Durgam *et al.* 2017).

The incidence of TEAEs was 81.7% (Nasrallah *et al.* 2017). TEAEs reported in at least 10% of patients were akathisia (15.5%), insomnia (13.3%), headache (12.8%), and weight increase (10.5%) (Table 34-6). Serious adverse events were reported in 82 patients (12.1%) during the open-label treatment period, including one death (suicide). The most common serious adverse events were worsening of schizophrenia (4.4%) and psychotic disorder (2.1%).

TABLE 34-6. Most frequent[a] treatment-emergent adverse events (TEAEs) during long-term (48-week) treatment with cariprazine ($N = 679$)

TEAE	*n* (%)
Akathisia	105 (15.5)
Insomnia	90 (13.3)
Headache	87 (12.8)
Weight increase	71 (10.5)
Anxiety	58 (8.5)
Tremor	47 (6.9)
Extrapyramidal disorder	45 (6.6)
Schizophrenia	39 (5.7)
Nausea	38 (5.6)
Restlessness	38 (5.6)
Dyspepsia	37 (5.4)
Nasopharyngitis	34 (5.0)

[a] Reported by [?] 5% of patients.

Source. Adapted from Nasrallah *et al.* 2017. Copyright (c) 2017, The Authors. Open Access: Creative Commons Attribution 4.0 International License (http://creativecommons.org/licenses/by/4.0/).

The mean increase in body weight was 1.58 kg (Table 34-7). A potentially clinically significant increase in body weight was seen in 27% of patients; a potentially clinically significant decrease was seen in 11% of patients. Mean changes from baseline to the end of the study in metabolic variables and other clinical laboratory values, blood pressure, and electrocardiographic variables were generally small. The mean increase in fasting glucose (4.5 mg/dL) was similar to that observed during the 6-week lead-in studies. Mean alanine transaminase and aspartate transaminase values increased slightly. Creatine kinase levels increased slightly during open-label treatment; however, a large standard deviation indicates that the data were highly variable. No patients' symptoms met criteria for Hy's law (regarding risk of fatal drug-induced liver injury). Mean prolactin levels decreased from baseline to the end of the study. The incidence of treatment-emergent parkinsonism (measured by the Simpson-Angus Scale) was 10.7%, and the incidence of treatment-emergent akathisia (measured by the Barnes Akathisia Rating Scale) was 17.8%. Ophthalmological testing revealed no significant ocular changes. There was no mean increase in the QTc interval. A greater-than-60-millisecond increase in the QTcB value occurred in 7 patients (1.0%) overall, whereas a greater-than-60-millisecond increase in the QTcF value occurred in 2 patients (0.3%) overall. Three patients (0.4%) had a postbaseline QTcB value greater than 500 milliseconds; one of these patients (0.2%) also had a postbaseline QTcF value greater than 500 milliseconds.

16-Week Open-Label Study in Bipolar Mania

In a 16-week study ($N = 402$) of open-label, flexible-dosage cariprazine (3-12 mg/day) in adult patients with bipolar mania (Ketter *et al.* 2018), the overall completion rate was 33%; 16% of patients discontinued the medication because of adverse events. The mean treatment duration was 57.7 days, and the mean cariprazine dosage was 6.2 mg/day. No deaths were reported.

The incidence of TEAEs was 83.3% (Ketter *et al.* 2018). TEAEs reported in at least 10% of patients were akathisia (32.6%), headache (16.7%), constipation (10.7%), and nausea (10.4%). On the basis of EPS rating scales, treatment-emergent parkinsonism and akathisia were observed in 8.7% of patients and 36.8% of patients, respectively. Although 37.6% patients had TEAEs of akathisia/restlessness, only 4.7% of patients discontinued cariprazine because of akathisia. Of new cases of akathisia/restlessness, 94% were reported during the first 4 weeks of treatment; only nine new cases were reported from week 5 to week 16. Most TEAEs of akathisia/restlessness (98%) were considered mild or moderate in severity and related to treatment. The mean body weight increase was less than 1 kg; 9.3% of patients had a [?] 7% gain in body weight, and a [?] 7% loss in body weight was reported in 3.5% of patients. Mean changes in laboratory values, vital signs, electrocardiographic results, and ophthalmological variables were generally small. Cariprazine treatment was not associated with an increase in prolactin levels.

26-Week Open-Label Study in Major Depressive Disorder

In a Phase III open-label, long-term (26-week), flexible-dosage (1.5-4.5 mg/day) multicenter study of cariprazine used adjunctively with antidepressant therapy in adult patients, the completion rates were 66% for patients who had completed a lead-in study ($n = 311$) and 36% for patients who had been newly recruited ($n = 131$) (Vieta *et al.* 2019). A total of 79.4% of patients experienced a TEAE, with 97.1% of these considered mild or moderate. The most common TEAEs were akathisia (15.9%) and headache (11.6%). Mean changes in clinical laboratory, cardiovascular, and ophthalmological variables were generally not clinically relevant. The most common TEAEs leading to discontinuation were akathisia (2.9%), restlessness (2.0%), anxiety (1.7%), and fatigue (1.2%). Two deaths occurred (one traffic accident and one completed suicide), both of which were considered unrelated to treatment.

High Dosage and Overdose

In premarketing clinical trials involving cariprazine in approximately 5,000 patients or healthy subjects, accidental acute overdosage (48 mg/day) was reported in one patient. This patient experienced orthostasis and sedation. The patient fully recovered the same day (Allergan 2022).

Use During Pregnancy and Lactation

There have been no well-controlled studies of cariprazine in pregnant women, but neonates whose mothers have been exposed to other antipsychotic medications during the third trimester of pregnancy are at risk for EPS and withdrawal symptoms following delivery (Allergan 2022).

Administration of cariprazine to rats during the period of organogenesis caused malformations, lower pup survival, and developmental delays at drug exposures less than the human exposure at the maximum recommended human dosage of 6 mg/day. However, cariprazine was not teratogenic in rabbits at doses up to 4.6 times the maximum recommended human dosage of 6 mg/day. Thus, some animal data suggest that cariprazine may cause fetal harm. Pregnant women should be advised of the potential risk to the fetus (Allergan 2022).

Conclusion

Cariprazine combines functional selectivity at D_3 and D_2 receptors, partial agonist activity at 5-HT_{1A} receptors, and antagonism at 5-HT_{2B} and, to a lesser extent, 5-HT_{2A} receptors. Cariprazine's receptor binding profile is unique, with the highest affinity and selectivity for D_3 receptors of any second-generation antipsychotic. The long half-life of its predominant circulating active metabolite, DDCAR, permits every-other-day dosing when lower dosages are required. Cariprazine is approved as a monotherapy for use in treating schizophrenia, bipolar I mania, and bipolar I depression and as an adjunctive therapy for major depressive disorder. Adverse reactions (incidence [?] 5% and at least twice the rate of placebo) listed in the product label and common to all four indications are EPS and akathisia. Cariprazine is relatively well tolerated in terms of weight gain, metabolic variables, and sedation/somnolence, and it has no deleterious effect on prolactin or the electrocardiogram QT interval.

This chapter is an update and revision of Albrahim S, Henry JH, Nemeroff CB: "Cariprazine," in *The American Psychiatric Association Publishing Textbook of Psychopharmacology*, 5th Edition. Edited by Schatzberg AF, Nemeroff CB. Washington, DC, American Psychiatric Publishing, 2017, pp. 831-853.

CHAPTER 35

Pimavanserin

Jeffrey Cummings, M.D., Sc.D.(HS)

Pimavanserin (Nuplazid) occupies a unique niche in the neuropsychopharmacological armamentarium. It was the first agent approved to treat any neuropsychiatric syndrome in any neurodegenerative disease. It is currently one of only two such agents (brexpiprazole is approved to treat agitation in Alzheimer's disease). Pimavanserin is approved by the FDA to treat hallucinations and delusions in Parkinson's disease. Given the high prevalence of neuropsychiatric symptoms in neurodegenerative disorders, it is remarkable that only one agent has been approved to treat this key aspect of these common conditions (Cummings 2021). Details of the drug's history, structure-activity relations, pharmacological profile, pharmacokinetics, indications and efficacy, side effects and toxicology, and drug-drug interactions are presented in this chapter.

Pimavanserin is currently available as a 10-mg tablet and a 34-mg capsule, and no generic equivalent products are marketed at present. The capsule may be swallowed whole or opened and sprinkled on certain soft foods for ease of administration (Acadia Pharmaceuticals 2023).

History and Discovery

Pimavanserin was discovered as the result of a rational discovery program. It was noted that the common feature of most atypical antipsychotics was that they were highly potent serotonin type 2A (5-HT$_{2A}$) receptor inverse agonists or antagonists and were less potent dopamine type 2 receptor antagonists. This finding led to the hypothesis that highly selective 5-HT$_{2A}$ receptor inverse agonists/antagonists might have antipsychotic properties with more desirable side-effect profiles compared with agents with concomitant dopamine receptor blockade. A functional receptor selection and amplification assay for 5-HT$_{2A}$ receptor inverse agonists using overexpression of 5-HT$_{2A}$ receptors in the embryonic mouse fibroblast cell line NIH/3T3 with a marker gene to permit signal detection with a colorimetric method was developed for high-throughput screening (Hacksell *et al.* 2014). Thirteen thousand small molecules were assessed; of 500 initial hits, 100 were shown to be 5-HT$_{2A}$ inverse agonists. One of these agents had the desired receptor engagement profile, with nearly 100-fold selectivity for 5-HT$_{2A}$ receptors over serotonin type 2B, serotonin type 2C (5-HT$_{2C}$), and serotonin type 6 receptors. The initial hit compound had poor oral availability. A lead optimization campaign was initiated to develop an orally available analogue; ACP-103 (pimavanserin/Nuplazid) was the product of the lead optimization enterprise (Hacksell *et al.* 2014).

Structure-Activity Relations

Pimavanserin tartrate salt has the chemical name urea, *N*-[(4-fluorophenyl)methyl]-*N*-(1-methyl-4-piperidinyl)-*N* -[[4-(2-methylpropoxy)phenyl]methyl]-, (2*R*,3*R*)-2,3-dihydroxybutanedioate (2:1) (Cruz 2017). The molecular formula of pimavanserin free base is $(C_{25}H_{34}FN_3O_2)_2$. The molecular weight of pimavanserin free base is 427.55 (Cruz 2017).

The 5-HT$_{2A}$ receptor is a G protein-coupled receptor that interacts with the G proteins and other transducing molecules (Sullivan *et al.* 2015). 5-HT$_{2A}$ inverse agonists block metabotropic glutamate receptors 2/3 and increase release of dopamine in mesolimbic and mesocortical brain regions (Sullivan *et al.* 2015; Wischhof and Koch 2016). The 5-HT$_{2A}$ receptor is widely distributed in the brain and is most abundant in the neocortex (Lopez-Gimenez and Gonzalez-Maeso 2018). This same receptor has been implicated in mediating the psychotogenic effects of hallucinogens such as lysergic acid diethylamide (LSD) that are 5-HT$_{2A}$ receptor agonists (Gonzalez-Maeso *et al.* 2008). The structure of pimavanserin and its position when docked in the 5-HT$_{2A}$ receptor are shown in Figure 35-1.

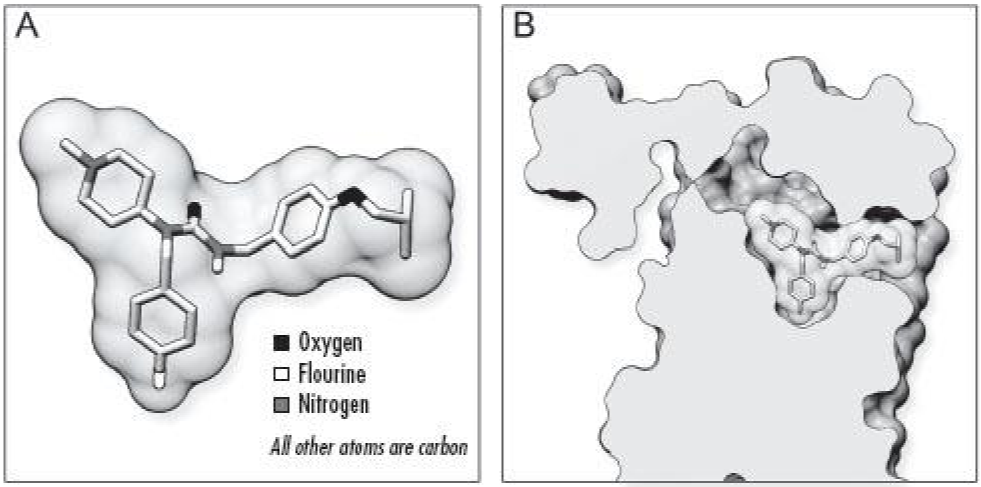

FIGURE 35-1. (A) Structure of pimavanserin and (B) pimavanserin docked in the binding pocket of the serotonin type 2A receptor.

Structure-activity relations for a receptor and its companion transmitter must be seen in the circuit context in which the receptor occurs. Human cognition and behavior are emergent properties of circuits, and the treatment effect at the circuit level is critical to the efficacy of a transmitter-based intervention (Krakauer *et al.* 2017; Mill *et al.* 2017). The circuit impact of a treatment for psychosis that occurs with different types of neurodegenerative disorders may result from a final common pathway for psychosis involving dysregulation of cortical and limbic pathways, including serotonergic, GABAergic, glutamatergic, and dopaminergic signaling. The imbalance in cortical and mesolimbic excitatory tone involves circuits with 5-HT_{2A} receptors across types of neurodegenerative disease, providing an opportunity for modulation of psychotic symptoms in multiple disorders with a 5-HT_{2A} inverse agonist/antagonist (Cummings *et al.* 2022). The 5-HT_{2A} receptor is well represented in the amygdala, a structure involved in emotional behavior and included in the circuits affected by many neurodegenerative disorders and plausibly involved in psychosis with neurodegenerative disorders (Bombardi 2014). Genetic studies have found correlations between specific polymorphisms of the 5-HT_{2A} receptor gene and the presence of psychotic and other behavioral symptoms in Alzheimer's disease (Holmes *et al.* 1998, 2007; Lam *et al.* 2004). These polymorphisms in the 5-HT_{2A} receptor may contribute to the variable occurrence of psychosis in patients with neurodegenerative disorders.

Pharmacological Profile

Pimavanserin exhibits inverse agonist/antagonist activity at the 5-HT_{2A} receptor and to a lesser extent at the 5-HT_{2C} receptor. Pimavanserin has a 100-fold lower affinity for 5-HT_{2C} than 5-HT_{2A} (Caraci *et al.* 2020; Hacksell *et al.* 2014). Unlike most other atypical antipsychotics, it lacks significant antagonism of adrenergic, dopaminergic, histaminergic, and muscarinic receptors (Yunusa *et al.* 2020).

Pimavanserin activity has been assessed in animal models used to interrogate possible antipsychotic profiles of an agent. In one study, pimavanserin attenuated head-twitch behavior and prepulse inhibition deficits induced in rats by a 5-HT_{2A} receptor agonist and reduced hyperactivity induced in mice by an *N*-methyl-D-aspartate receptor noncompetitive antagonist, thereby demonstrating effects consistent with a 5-HT$_{2A}$ receptor mechanism of action in vivo and antipsychotic-like efficacy (Vanover *et al.* 2006).

In an animal model relevant to Parkinson's disease and to psychosis, animals with bilateral 6-hydroxydopamine lesions of the substantia nigra displayed motoric impairments characteristic of humans with Parkinson's disease and exhibited augmented head twitches, increased amphetamine-induced locomotor activity, and disrupted prepulse inhibition, behavioral indices frequently used to assess antipsychotic activity in animal models. Pimavanserin reversed the psychosis-like behavioral deficits without exacerbating the motor deficits. The selective 5-HT$_{2A}$ inverse agonist M100907, but not the selective 5-HT$_{2C}$ inverse agonist SB 242084, paralleled the effects of pimavanserin, supporting the conclusion that the effects were mediated through 5-HT$_{2A}$ receptors (McFarland *et al.* 2011).

Animal studies relevant to the treatment of psychosis in neurodegenerative disorders have been pursued. Mice that received an intracerebroventricular infusion of the amyloid b$_{(25-35)}$ peptide fragment showed Alzheimer's disease-like histopathology and a psychosis-related behavioral phenotype with enhanced responses to the psychostimulants 2,5-dimethoxy-4-iodoamphetamine hydrochloride and amphetamine as well as disrupted prepulse inhibition (Price *et al.* 2012). Treatment with pimavanserin prevented 2,5-dimethoxy-4-iodoamphetamine hydrochloride-induced head twitches, reversed the augmented locomotor response to amphetamine, and normalized prepulse inhibition. These observations suggest that amyloid-b pathology may induce alterations in serotonergic function that underlie a psychosis-like phenotype and that can be normalized by pimavanserin. Pimavanserin has also been reported to reduce amyloid-b protein and improve cognition in transgenic models of Alzheimer's disease in which this protein is overproduced (Yuede *et al.* 2021).

Pharmacokinetics

Pimavanserin was well tolerated in Phase I and Phase II studies; 100 mg qd was identified as the maximum tolerated dosage. Pimavanserin exhibits dose-proportional plasma exposure over a wide range of doses, and no food effects on bioavailability have been found (Hacksell *et al.* 2014). A PET study using the 5-HT$_{2A}$ radioligand 3-*N*-[^{11}C]-methylspiperone (^{11}C-NMSP) demonstrated that a 10-mg dose nearly completely occupied the visualized frontal lobe 5-HT$_{2A}$ receptors, and a 20-mg oral dose produced maximal binding in healthy volunteers (Nordstrom *et al.* 2008).

The half-life of pimavanserin is relatively long at 55-60 hours. Pimavanserin is detectable in the serum within 1 hour of oral administration, and the time to maximal serum concentration for a single 34-mg dose (the standard dose used in clinical studies) is 6-8 hours (Cruz 2017; Nordstrom *et al.* 2008; Yunusa *et al.* 2020). Pimavanserin is highly bound to plasma protein (approximately 95%).

Pimavanserin is metabolized primarily in the liver by the cytochrome P450 (CYP) enzymes 3A4 and 3A5 and to a lesser extent by CYP2J2, CYP2D6, and other CYP and flavin-containing monooxygenase enzymes. It neither inhibits nor induces CYP3A4 activity. Maximal plasma concentrations are increased 1.5-fold by strong CYP3A4 inhibitors such as ketoconazole. There is a single dominant metabolite--*N*-desmethylated pimavanserin (AC-279)--that has a half-life of 200 hours (Cruz 2017; Yunusa *et al.* 2020). Approximately 1% of the parent compound is excreted unchanged in the urine and feces (Cruz 2017). The pharmacokinetics of pimavanserin are not known to be affected by age, sex, ethnicity, or weight; the number of patients in ethnic minority groups included in trials is small. Doses of pimavanserin need not be adjusted in patients with mild to moderate renal impairment; use of pimavanserin is not recommended in those with severe renal impairment or hepatic compromise (Cruz 2017).

Indications and Efficacy

Hallucinations and Delusions in Parkinson's Disease Psychosis

Pimavanserin is approved by the FDA for the treatment of hallucinations and delusions associated with Parkinson's disease with and without dementia. The efficacy of pimavanserin for the treatment of impulse-control disorders in Parkinson's disease, depression in Parkinson's disease, and insomnia in PTSD is being explored in clinical trials (see ClinicalTrials.gov).

Pimavanserin was assessed as an adjunctive to antidepressant treatment for major depressive disorder and was found not to have benefit in this setting. In a Phase II trial of pimavanserin for the treatment of negative symptoms in patients with schizophrenia, the active treatment group showed significantly greater improvement compared with the placebo group on the primary outcome, the Negative Symptom Assessment-16 (Business Wire 2019).

With its approval in 2016 for the treatment of hallucinations and delusions associated with Parkinson's disease psychosis (PDP), pimavanserin became the first psychotropic agent approved to treat any neuropsychiatric syndrome in any neurodegenerative disease. Brexpiprazole has since been approved for treatment of agitation associated with dementia due to Alzheimer's disease. The receptor profile of pimavanserin--5-HT_{2A} inverse agonism/antagonism and an absence of antagonism for dopamine receptors--suggested that it would have a useful role in the treatment of PDP. Traditional dopamine-blocking antipsychotics exaggerate parkinsonism (Graham *et al.* 1998). Nonclinical studies showed that pimavanserin ameliorated psychosis-like behaviors in rodent models with parkinsonism (McFarland *et al.* 2011).

A 28-day randomized, placebo-controlled Phase II study of pimavanserin for PDP showed no difference between drug and placebo on the Scale for the Assessment of Positive Symptoms (SAPS) total score. Pimavanserin-treated patients had significantly greater improvement on the SAPS measures of hallucinations and delusions compared with those taking placebo. The Unified Parkinson's Disease Rating Scale domains of delusions and hallucinations were significantly more improved in patients receiving pimavanserin compared with those receiving placebo. Administration of pimavanserin was not associated with worsening of motor function, sedation, or hypotension (Meltzer *et al.* 2010).

Many items on the SAPS are symptoms that are common in schizophrenia but rare in Parkinson's disease. To advance a scale more appropriate for use in PDP trials, Voss *et al.* (2013) developed the shortened Scale for Assessment of Positive Symptoms for Parkinson's Disease (SAPS-PD). This tool was used in a pivotal trial of pimavanserin for PDP.

This pivotal trial of pimavanserin for the treatment of PDP was a 6-week randomized, double-blind, parallel-group, placebo-controlled trial of pimavanserin (40 mg/day [Cummings *et al.* 2014]). All eligible participants entered a 2-week lead-in period with psychosocial therapy to identify patients responsive to nonpharmacological treatment. Following the lead-in period, 199 participants were randomly assigned to active treatment or placebo. After 6 weeks of treatment, the pimavanserin-treated group had a significantly greater decrease in SAPS-PD score ([?] 5.79 points) compared with the placebo group ([?] 2.73 points). Secondary outcomes, including scores on the Clinical Global Impression--Severity (CGI-S) and Clinical Global Impression--Improvement (CGI-I) scales as well as on measures of caregiver burden, improved significantly in the active treatment group. Scores on measures completed by central trial raters, site raters, and caregivers provided convergent validity of the antipsychotic effects. Sleep was notably improved in those receiving pimavanserin (Cummings *et al.* 2014; Kitten *et al.* 2018). There was no worsening of motor function in the active treatment group. There were more dropouts in the pimavanserin group, in part because of hallucinations or delusions that occurred within 10 days of patients starting the study drug.

An exploratory outcome of the PDP trial was the assessment of nighttime sleep quality and daytime wakefulness with the Scales for Outcomes in Parkinson's Disease--Sleep and Scales for Outcomes in Parkinson's Disease--Daytime Sleepiness (SCOPA-DS) (Marinus *et al.*

2003). Significantly greater improvement in both nighttime sleep quality and daytime sleepiness was observed in the group receiving pimavanserin compared with the group receiving placebo (Cummings *et al.* 2014). Pooled data from two trials provided additional evidence showing a sleep benefit in patients being treated for PDP with pimavanserin (Patel *et al.* 2018). Polysomnographic studies in healthy adult volunteers receiving pimavanserin showed increased slow-wave sleep and decreased nocturnal awakenings without effects on other sleep parameters (Ancoli-Israel *et al.* 2011). Pimavanserin significantly reduced insomnia in a trial of major depressive disorder in which it was given as adjunctive therapy (Jha *et al.* 2020). 5-HT$_{2A}$ receptors may play an important role in sleep and wakefulness, and receptor antagonists have been investigated as potential hypnotics (Al-Shamma *et al.* 2010; Landolt and Wehrle 2009).

An open-label investigation of pimavanserin in patients with Parkinson's disease and major depressive disorder demonstrated that 60% of patients showed a greater than 50% reduction in depression rating scale scores, and 44% experienced remission of depressive symptoms (DeKarske *et al.* 2020). Further exploration of the effects of pimavanserin on mood changes in Parkinson's disease and other neurodegenerative diseases may be warranted.

Hallucinations and Delusions in Alzheimer's Disease Psychosis

Following its approval to treat PDP, pimavanserin was assessed in patients with hallucinations and delusions associated with Alzheimer's disease psychosis (ADP). In a double-blind, placebo-controlled, parallel-group trial, 181 nursing home residents with probable or possible Alzheimer's disease and psychosis were randomly assigned to receive pimavanserin (34 mg/day) or placebo (Ballard *et al.* 2018). The primary outcome was the difference between the drug and placebo in change from baseline on the Neuropsychiatric Inventory--Nursing Home version at week 6 of treatment. Sustained benefit and safety/tolerability were assessed through week 12. At week 6, there was a significant difference between drug and placebo in favor of pimavanserin ([?] 3.76 points for pimavanserin versus [?] 1.93 points for placebo). Patients in the placebo arm continued to improve during weeks 6-12, and the superiority of pimavanserin was not sustained to week 12. A secondary analysis of patients with more severe psychosis (i.e., those [$n = 57$] with baseline Neuropsychiatric Inventory--Nursing Home version psychosis scores > 12) found that this subgroup had a more robust treatment response, with 88.9% of patients receiving pimavanserin showing a scale score improvement of [?] 30% (vs. 43.3% [$P < 0.001$] of patients receiving placebo) and 77.8% (vs. 43.3% [$P = 0.008$]) showing [?] 50% improvement (Ballard *et al.* 2019). Patients who had at least a 50% reduction in psychosis scores experienced a concomitant significant reduction in agitation; those with less robust responses on psychosis measures had no significant reduction in agitation (Ballard *et al.* 2020). This finding suggests that pimavanserin can be used in the treatment of agitation when psychosis is present but may not be effective in reducing agitation when there is no associated psychosis. Pimavanserin is not approved by the FDA for the treatment of ADP or for the treatment of agitation.

Dementia-Related Psychosis

Pimavanserin was assessed in a clinical trial for dementia-related psychosis (DRP). The pivotal clinical trial of pimavanserin for PDP excluded patients with dementia; all participants had Mini-Mental State Examination (MMSE) scores higher than 20 (Cummings *et al.* 2014). A subsequent analysis showed that patients with greater cognitive impairment (MMSE scores of 21-24) had significantly greater reductions on the SAPS-PD than those with no cognitive changes or milder cognitive changes (MMSE scores of 25-30) (Espay *et al.* 2018). This finding suggested that pimavanserin could have a role in the treatment of hallucinations and delusions associated with PDP in patients with cognitive impairment.

A retrospective (~1 year) analysis comparing pimavanserin versus quetiapine in the treatment of psychosis in patients with Parkinson's disease and patients with Lewy body dementia found comparable efficacy for the two agents; however, compared with patients taking quetiapine, those taking pimavanserin showed lower discontinuation rates early in the treatment period and higher discontinuation rates later in the treatment period (Horn *et al.* 2019).

Study data suggesting pimavanserin's efficacy in the treatment of cognitive impairment in PDP, psychosis in Alzheimer's disease, and psychosis in dementia with Lewy bodies provided the foundation for the study of pimavanserin for DRP. HARMONY was a randomized discontinuation trial involving patients with five types of dementia with psychosis: Alzheimer's disease, Parkinson's disease with dementia, dementia with Lewy bodies, frontotemporal lobar degeneration, and vascular dementia (Foff *et al.* 2020; Tariot *et al.* 2021) (Figure 35-2). Eligible participants entered a 12-week open-label treatment period with pimavanserin. Other types of antipsychotic treatment were not allowed in the trial. Participants whose symptoms met the response criteria (a > 30% reduction in the SAPS hallucinations plus delusions total score, and a CGI-I score of 1 [very much improved] or 2 [much improved] at week 8 and at week 12) were randomly assigned to continue taking pimavanserin or to start taking placebo. During the open-label period, 70% of the participants had symptoms that met the response criteria at week 8, and 88% of those patients demonstrated a sustained response at week 12.

The primary outcome of the HARMONY trial was time to relapse, defined as follows: 1) a > 30% worsening in the SAPS hallucinations plus delusions total score and a CGI-I score of 6 (much worse) or 7 (very much worse), 2) hospitalization due to DRP, 3) stopping of the study drug or withdrawal from the study due to lack of efficacy, or 4) use of other antipsychotics for the treatment of DRP. A prespecified interim analysis was based on the hazard ratio for relapse. The interim analysis revealed significant efficacy of pimavanserin over placebo, and the study was stopped early for definitive efficacy on the prespecified outcomes. The PDP group had a significant response to pimavanserin; other dementia groups had too few participants to allow assessment of efficacy within specific diagnoses (Tariot *et al.* 2021). Pimavanserin is not approved to treat DRP.

Major Depressive Disorder

Pimavanserin was assessed in a randomized, double-blind, placebo-controlled multicenter study of patients with major depressive disorder and an inadequate response to a selective serotonin reuptake inhibitor or a serotonin-norepinephrine reuptake inhibitor (Fava *et al.* 2019). In stage 1 of a sequential parallel comparison design, patients were randomly assigned in a 3:1 ratio to placebo or pimavanserin added to ongoing selective serotonin reuptake inhibitor or serotonin-norepinephrine reuptake inhibitor therapy; in stage 2 (week 5), placebo nonresponders were once again randomly assigned to placebo or pimavanserin for an additional 5 weeks. Significantly greater improvement with pimavanserin compared with placebo was observed on the 17-item Hamilton Rating Scale for Depression (Ham-D-17) total score and the Sheehan Disability Scale score. The difference between drug and placebo was evident at week 1. The most common adverse events with pimavanserin were dry mouth, nausea, and headache. A subanalysis of the anxiety/somatization factor of the Ham-D-17 showed a significant difference between drug and placebo in favor of pimavanserin. Patients with higher anxiety/somatization factor scores had more robust responses (Papakostas *et al.* 2020). However, two Phase III parallel-group trials of pimavanserin for treatment-resistant major depressive disorder failed to meet the primary outcome of a difference between drug and placebo on the Ham-D-17. Pimavanserin is not approved to treat major depressive disorder.

Negative Symptoms of Schizophrenia

Pimavanserin has been preliminarily assessed for efficacy in treating schizophrenia. In a randomized, double-blind 6-week trial, patients with chronic schizophrenia and a recent exacerbation of psychotic symptoms received pimavanserin (20 mg/day) as an

augmenting agent with low-dosage risperidone or haloperidol. The study showed that the combination of pimavanserin and low-dosage risperidone (2 mg/day) had the same efficacy as high-dosage risperidone (6 mg/day) and produced fewer side effects (weight gain, hyperprolactinemia). Pimavanserin combined with haloperidol 2 mg/day was equal in efficacy to haloperidol 2 mg/day without pimavanserin; however, participants taking the combination had fewer extrapyramidal effects. All treatment groups showed significantly greater reductions in the Positive and Negative Syndrome Scale total score compared with the placebo groups (Meltzer *et al.* 2012).

Open-label observations of pimavanserin for treatment-refractory hallucinations and delusions in patients with schizophrenia or schizoaffective disorder suggest that pimavanserin may be useful in this population (Nasrallah *et al.* 2019).

Use of pimavanserin in first-episode schizophrenia will be explored to determine whether there is a serotonergic subtype of schizophrenia that responds preferentially to 5-HT_{2A} inverse agonists/antagonists such as pimavanserin (Baltzersen *et al.* 2020; Nasrallah *et al.* 2019).

Pimavanserin is being assessed in a treatment trial for negative symptoms of schizophrenia (Krogmann *et al.* 2019). The combination of antipsychotic efficacy and dopamine release in the limbic cortex and mesocortex makes pimavanserin an attractive candidate for this indication.

Pimavanserin is not approved for use in schizophrenia.

Side Effects and Toxicology

All antipsychotics have boxed and bolded warnings that elderly patients with DRP treated with antipsychotic drugs are at increased risk for death. The manufacturer's current label (Acadia Pharmaceuticals 2023) states that pimavanserin is not approved for treatment of patients with dementia who experience psychosis unless their hallucinations and delusions are related to Parkinson's disease. This cautionary labeling requires that clinicians be vigilant when using this medication for DRP (Mathis *et al.* 2017). The causes of death among dementia patients treated with antipsychotics have been variable and have not been mechanistically related to the receptor profiles of antipsychotic agents. A recent comparison of mortality in patients with Parkinson's disease treated with pimavanserin or quetiapine found fewer deaths among those receiving pimavanserin (Mosholder *et al.* 2020); this suggests that pimavanserin may be less likely than other antipsychotics to increase mortality rates, but additional studies are needed.

Pimavanserin prolongs the cardiac QT interval, and its use should be avoided in patients with known QT prolongation or in combination with other drugs known to prolong the QT interval, including antiarrhythmics (e.g., quinidine, procainamide, amiodarone, sotalol), certain antipsychotic medications (e.g., ziprasidone, chlorpromazine, thioridazine), and certain antibiotics (e.g., gatifloxacin, moxifloxacin) (Caraci *et al.* 2020). Pimavanserin should be avoided in patients with a history of cardiac arrhythmias or with other conditions--such as symptomatic bradycardia, hypokalemia or hypomagnesemia, or congenital prolongation of the QT interval--that may increase the risk of torsades de pointes and/or sudden death (Acadia Pharmaceuticals 2023).

Common adverse reactions to pimavanserin with an incidence [?] 5% and at least twice the rate observed in a placebo group include peripheral edema (7% of patients taking pimavanserin 34 mg/day vs. 2% of those taking placebo) and confusional state (6% of patients taking pimavanserin 34 mg/day vs. 3% of those taking placebo) (Acadia Pharmaceuticals 2023).

Drug-Drug Interactions

Pimavanserin's effect on the QT interval suggests possible adverse drug interactions with antiarrhythmics (including quinidine, procainamide, amiodarone, and sotalol) and antipsychotic medications (e.g., ziprasidone, chlorpromazine, thioridazine) or antibiotics (e.g., gatifloxacin, moxifloxacin) that may induce QT prolongation (Acadia Pharmaceuticals 2023). Pimavanserin is metabolized through the CYP450 hepatic enzyme system. Strong CYP3A4 inhibitors (e.g., itraconazole, ketoconazole, clarithromycin, indinavir) may increase pimavanserin levels, requiring a reduction in dosage (the current recommendation is to reduce the dosage to 10 mg once daily) to avoid toxicity. Strong or moderate CYP3A4 inducers (e.g., rifampin, carbamazepine, phenytoin, St. John's wort) may reduce pimavanserin levels, decreasing its efficacy and requiring a compensatory increase in dosage (Acadia Pharmaceuticals 2023); concomitant use of pimavanserin is not recommended with these agents.

Conclusion

Pimavanserin is a selective 5-HT_{2A} inverse agonist/antagonist approved to treat PDP. In clinical trials, it reduced hallucinations and delusions associated with PDP and ADP. Pimavanserin occupies a unique niche in the repertoire of neuropsychiatric agents as the only drug approved to treat psychosis in any neurodegenerative disorder. Pimavanserin is given in a single dose of 34 mg/day. It has a long half-life of approximately 55-60 hours. It can produce QT interval prolongation and should not be given to patients receiving drugs that may prolong the QT interval or to patients with a history of arrhythmias or QT prolongation. Pimavanserin may confer sleep benefits. It is being explored for other indications, including ADP and negative symptoms of schizophrenia.

CHAPTER 36

Management of Psychiatric Medication-Induced Movement Disorders

Laura Marsh, M.D.

Acute and chronic movement disorders are a common side effect of medications used to treat psychiatric conditions. Antipsychotic medications that block dopamine D_2 receptors are recognized for this feature. Other psychiatric medications, including those that do not block dopamine receptors, can also cause clinically significant motor side effects, particularly tremor, and warrant consideration in the differential diagnosis of acquired abnormal movements. Regardless of the offending agent, treatment of medication-induced movement disorders relies on an awareness of which medications have this potential, characterization of the abnormal movements and the timing of their onset, and knowledge of pharmacological and nonpharmacological treatments.

This chapter addresses evaluation and management of movement disorder side effects caused by antipsychotic and other psychiatric medications. Common and familiar to most clinicians, the acute, subacute or chronic, and tardive motor syndromes induced by dopamine D_2-receptor blocking (DRB) antipsychotics provide a framework for describing the clinical phenomena of the different motor syndromes, conducting a differential diagnosis that includes the range of psychiatric and nonpsychiatric medications or other medical explanations, and initiating treatment. Because these iatrogenic movement disorders are underrecognized and can be associated with distress, falls, confusion, injuries, and harmful prescribing cascades, the above approach informs prescribing practices that mitigate risk for and manage drug-induced movement disorders.

History

Occurrence of abnormal movements as a side effect of psychiatric medications is inseparable from the early development of agents used to treat psychosis. This background is detailed in Chapter 25 ("Classic Antipsychotic Medications"). Notably, the terms used to describe drug-induced movement disorders and their inciting drugs have influenced drug development and patient care. In 1952, the discovery of chlorpromazine's antipsychotic effects (Delay and Deniker 1952; Laborit *et al.* 1952) was associated with recognition of its parkinsonian side effects (i.e., rigidity, bradykinesia, and tremor). In 1954, drug-induced parkinsonism (DIP) was formally described in patients treated with chlorpromazine and reserpine, a second-line antihypertensive agent that blocks vesicular monoamine transporter 2 (VMAT2) and results in monoamine depletion (Bergouignan and Regnier 1954; Steck 1954). In 1955, after Delay and Deniker proposed the term *neuroleptic* to the French Academy of Medicine to refer to the neurological side effects of parkinsonism, affective indifference, and emotional neutrality, chlorpromazine and other drugs producing similar effects were classified as neuroleptics, from the ancient Greek word meaning "one that grips the nerve" (Fielding and Lal 1978). A few years later, in 1959, descriptions of *tardive syndromes* (i.e., the long-term motor side effects from so-called neuroleptic drugs) were published (Lopez-Munoz *et al.* 2005; Sigwald *et al.* 1959). Although psychiatric medications other than these agents were subsequently found to cause movement disorders (Table 36-1), the prevailing focus has been on the role of this original group of DRB antipsychotic and monoamine-depleting agents (Blanchet and Kivenko 2016) in inducing abnormal movements.

TABLE 36-1. Medications known to cause movement disorders

Type of movement disorder	Neuropsychiatric medications	Other medications
Acute dystonic reactions	DRB antipsychotics	DRB antiemetic/promotility agents (e.g., clebopride, metoclopramide, prochlorperazine, promethazine)
	SSRIs	Antimalarial agents (e.g., quinine)
	Mood stabilizers or antiepileptics (e.g., carbamazepine, phenytoin, valproate)	Albendazole
	Opioids	Cetirizine
	Methylphenidate	Foscarnet
	Rivastigmine	Anesthetics (e.g., propofol, sevoflurane)
Gabapentin		

Note. DRB = dopamine D_2-receptor-blocking; MAOIs = monoamine oxidase inhibitors; SNRIs = serotonin-norepinephrine reuptake inhibitors; SSRIs = selective serotonin reuptake inhibitors; TCAs = tricyclic antidepressants.
Source. Adapted from Duma and Fung 2019; Friedman 2020; Zhou *et al.* 2022.

Type of movement disorder	Neuropsychiatric medications	Other medications
Akathisia	DRB antipsychotics	DRB antiemetic/promotility agents
	Antidepressants (SSRIs > SNRIs, MAOIs, TCAs)	DRB calcium channel blockers (e.g., cinnarizine, flunarizine)
	Mood stabilizers or antiepileptics (e.g., carbamazepine, pregabalin, valproate)	Azithromycin
	Buspirone	Sumatriptan
	Lithium	Methyldopa
	Tetrabenazine	Levodopa
	Dopamine agonists	
Tremor (nonparkinsonian)	Antidepressants (SSRIs > TCAs)	DRB antiemetics
	Lithium	Thyroid hormone replacement
	Mood stabilizers or antiepileptics (e.g., carbamazepine, phenytoin, valproate)	Bronchodilators
	Withdrawal from benzodiazepines, ethanol, or opiates	Amiodarone

Note. DRB = dopamine D_2-receptor-blocking; MAOIs = monoamine oxidase inhibitors; SNRIs = serotonin-norepinephrine reuptake inhibitors; SSRIs = selective serotonin reuptake inhibitors; TCAs = tricyclic antidepressants.

Source. Adapted from Duma and Fung 2019; Friedman 2020; Zhou *et al.* 2022.

Type of movement disorder	Neuropsychiatric medications	Other medications
	Immunosuppressants (e.g., cyclosporine, tacrolimus)	
Parkinsonism	DRB antipsychotics	DRB antiemetics
	Dopamine-depleting agents (e.g., deutetrabenazine, reserpine, tetrabenazine, valbenazine)	DRB calcium channel antagonists (e.g., cinnarizine, flunarizine)
	Mood stabilizers or antiepileptics (e.g., lamotrigine, levetiracetam, phenytoin, pregabalin, valproate)	Chemotherapy drugs (e.g., adriamycin, arabinoside, cyclophosphamide, cystosine, doxorubicin, etoposide, paclitaxel, vincristine)
	Antidepressants (SSRIs, MAOIs)	
Lithium		
Tardive movements	DRB antipsychotics	DRB antiemetic/promotility agents

Note. DRB = dopamine D_2-receptor-blocking; MAOIs = monoamine oxidase inhibitors; SNRIs = serotonin-norepinephrine reuptake inhibitors; SSRIs = selective serotonin reuptake inhibitors; TCAs = tricyclic antidepressants.

Source. Adapted from Duma and Fung 2019; Friedman 2020; Zhou *et al.* 2022.

Type of movement disorder	Neuropsychiatric medications	Other medications
SSRIs (if prior use of antipsychotics)		
Myoclonus and asterixis	Antidepressants--all types Clozapine, other antipsychotics	--
Mood stabilizers or antiepileptics (e.g., gabapentin, lamotrigine, topiramate, valproate)		

Note. DRB = dopamine D_2-receptor-blocking; MAOIs = monoamine oxidase inhibitors; SNRIs = serotonin-norepinephrine reuptake inhibitors; SSRIs = selective serotonin reuptake inhibitors; TCAs = tricyclic antidepressants.
Source. Adapted from Duma and Fung 2019; Friedman 2020; Zhou *et al.* 2022.

The hypothesized relationship between the therapeutic effect of antipsychotic agents and the drug-induced neuroleptic syndrome, and parkinsonism specifically, is also noteworthy. Some (Flugel 1953; Haase 1954) contended that these neurological side effects were necessary for the antipsychotic efficacy of chlorpromazine. Accordingly, clinical potency was titrated to occurrence of DIP in some drugs developed to treat psychosis (Lopez-Munoz *et al.* 2005). This theory, debated throughout the 1950s and 1960s (e.g., Brooks 1956), ultimately was not substantiated by a double-blind, placebo-controlled trial by Guttmacher (1964) showing comparable antipsychotic efficacy and a lower incidence of neurological side effects with thioridazine as compared with chlorpromazine and fluphenazine. Multiple subsequent studies further showed that antipsychotics at dosages greater than the "neuroleptic threshold" (i.e., the lowest dosage that causes a clinically detectable increase in signs of a hypokinetic-rigid syndrome) are likely to increase motor symptoms but confer no additional therapeutic benefit (Angus and Simpson 1970; Baldessarini *et al.* 1988; McEvoy *et al.* 1991). Nonetheless, the perception that the drug-induced neuroleptic syndrome was a marker of antipsychotic efficacy persisted and influenced clinical practice. For example, when clozapine was first synthesized in 1959, it was not considered a potential antipsychotic agent because it did not induce motor side effects. Later, despite clozapine's demonstrated efficacy as a treatment for schizophrenia, its release for clinical use in Europe was delayed until 1972 because of the popular belief that antipsychotic effects were not possible without associated parkinsonism (Hippius 1989; Lehmann and Ban 1997).

Clinical attention to psychiatric medication-induced movement disorders continues to be influenced by the nomenclature used for antipsychotic medications (King and Voruganti 2002). Most notable is the impact of the term *neuroleptic*, which refers to an adverse side effect rather than a beneficial pharmacological effect. Yet, the term *neuroleptic* is often used to denote antipsychotic medications in general, and antipsychotics that cause parkinsonism in particular. These agents, also known as classic, traditional, or conventional antipsychotics, are called first-generation antipsychotics (FGAs) in this chapter. A demand for safer and more tolerable antipsychotics led to development of the second-generation antipsychotics (SGAs), which were also called atypical or novel antipsychotics because of their lower propensity to cause abnormal movements. Although different mechanisms of action influence the relative risk for each SGA to induce movement abnormalities, a general perception of their improved safety was associated with a threefold increase in SGA prescribing, including for off-label uses in vulnerable populations such as the elderly and children and by nonpsychiatric clinicians (Friedman 2012). These prescribing patterns underscore the relevance of standardized baseline and ongoing follow-up assessments to prevent and manage drug-induced movement disorders (American Psychiatric Association 2021; Pringsheim *et al.* 2018).

A host of psychiatric and nonpsychiatric drugs, with and without influences on dopamine, can cause abnormal movements (see Table 36-1). When psychiatric patients develop abnormal movements, especially parkinsonism, causal agents aside from FGAs and SGAs can be overlooked when the focus is on "neuroleptic" drugs (Chouksey and Pandey 2020). Valproate, lithium, and DRB antiemetic agents (e.g., metoclopramide, promethazine) are common examples. Antiepileptic drugs, used to treat seizures, chronic pain, and primary psychiatric conditions, are associated with a broad range of abnormal movements that overlap with psychiatric symptoms or antipsychotic-induced movements (e.g., tics with lamotrigine; parkinsonism with valproate and gabapentinoids) (Pacheco-Paez *et al.* 2020; Zhou *et al.* 2022).

Finally, movement disorder specialists argue that the term *extrapyramidal* is obsolete, contending that its inexact and global use as both a descriptor and a cause of abnormal movement phenomena in psychiatric patients discourages accurate diagnosis and appropriate treatment (Obeso 2019). That is, the synonymous and interchangeable use of the terms *extrapyramidal drugs, movements, syndromes, and disorders* in connection with DRB antipsychotics, basal ganglia motor networks, and effects on basal ganglia function restricts consideration of the role of other psychiatric and nonpsychiatric medications and motor systems in drug-induced motor phenomena. Given that many psychiatric drugs cause abnormal movements, a preferred approach is to describe, rather than explain, the observed clinical motor phenomena (e.g., tremor at rest, akathisia, dystonia) and their timing; pursue the differential etiologies, including primary or drug-induced conditions; and implement appropriate interventions. Such an approach facilitates serial evaluations and consideration of whether the observed drug-induced movements represent a de novo movement disorder versus an exacerbated primary movement disorder, such as Parkinson's disease, essential tremor, or cervical dystonia. Notably, offending medications may "unmask" signs and symptoms of a primary movement disorder that is emerging but not yet diagnosed. In the assessment of movement disorders, the extrapyramidal system can be best conceptualized as referring to all of the various neural networks that modulate motor movement and coordination and that are distinct from the pyramidal system (i.e., the corticospinal and corticobulbar pathways that pass through the medullary pyramids and directly innervate lower motor neurons). Accordingly, to avoid imprecision and promote discovery, the term *extrapyramidal* is no longer accepted in the journal *Movement Disorders* (Obeso 2016).

Movement Disorder Phenomenology

A systematic approach to treatment of psychiatric medication-induced movement disorders starts with clarification of the chronological onset of the movements relative to the time of ingestion of or exposure to the potential offending agent and characterization of the abnormal movements. This is accomplished by eliciting the history of the onset and course of the movements and conducting a physical examination. Information on current and remote medications and family history, also key elements, often require data from other sources.

Timing of Abnormal Movements

Drug-induced movement disorders are categorized according to the timing of the onset and resolution of the abnormal movements relative to the timing of exposure to the medication. *Acute disorders* appear within minutes to days of drug exposure and can be life threatening. Examples are acute dystonic reactions, akathisia, and tremor. This chapter does not discuss serotonin syndrome, neuroleptic malignant syndrome (NMS), or the akinetic crisis of Parkinson's disease, which can also occur with psychiatric

medications and involve abnormal motor movements. *Subacute disorders*, exemplified by DIP, occur days to weeks after drug exposure. Some acute disorders can also have a subacute onset; levodopa-induced dyskinesia, a subacute condition that is not addressed in this chapter, is an example. Abnormal movements that persist for several months while an individual is taking an offending agent are considered *chronic disorders*. Diagnosis of a *tardive syndrome or disorder* is made only in the context of known exposure to DRB agents. Tardive disorders are defined as abnormal movements that persist after discontinuation of any DRB medication or that subside when the DRB medication dosage is increased. Onset tends to occur after prolonged exposure (typically defined as after 3 months, or after 1 month for adults older than 60 years). However, movements may not be observed for several months to years of ongoing exposure. The most common tardive movement disorder, referred to as "classic tardive dyskinesia" (TD), involves oral-buccal-lingual (OBL) dyskinetic movements. Other tardive movement phenomena may be present, with or without concurrent TD. Other relatively common tardive syndromes include tardive dystonia, tardive akathisia, and withdrawal-emergent syndrome. Withdrawal dyskinesias or akathisias occur after medication discontinuation or dosage reduction and usually resolve after about 6 weeks. Movements still present after that time likely represent a tardive condition.

Clarification of the timing of exposure to the drug relative to the timing of onset and resolution of drug-induced movements is essential for accurate diagnosis and effective treatment. A single cross-sectional examination and patient interview may provide inadequate information. Serial motor evaluations, collateral informants, and pharmacy records provide critical data for diagnosis, especially for patients who have been exposed to offending medications for longer durations. Notably, acute, subacute, and chronic *medication-induced abnormal movements* should subside and resolve when the offending drug is removed or reduced, even if full resolution of the movements occurs gradually after cessation of the medication. By contrast, *tardive syndromes* emerge or persist when the offending drug is discontinued or reduced and subside or diminish when the dosage is increased.

Types of Abnormal Movements

Abnormal motor phenomena, regardless of etiology, are classified as either hyperkinetic or hypokinetic, and their related movement disorder syndromes fall into two broad categories: hyperkinetic and akinetic-rigid conditions. In *hyperkinetic* disorders, there are excessive involuntary movements, also called *dyskinesias*, that are distinguished from one another by the presence or absence of rhythmic and stereotyped movements. Tremor, dystonia, chorea, tics, and myoclonus are the most common types of dyskinesias. Rhythmic hyperkinetic movements suggest a tremor or tremor-like disorder. Tremors are further characterized by how they occur, such as at rest, with certain postures, or during active movements. Stereotyped movements, by definition, occur repeatedly but are not rhythmic. Dystonias are slow stereotyped movements, whereas motor tics present as rapid stereotyped movements. Hyperkinetic movements that lack both rhythmicity and stereotypy include chorea, ballismus, and myoclonus; these are distinguished by their different speeds.

Hypokinetic or akinetic-rigid syndromes are characterized by their paucity of spontaneous voluntary movements. *Hypokinetic* phenomena include a reduction in the amplitude and speed of movement (bradykinesia), a lack of movement or an impairment

in the ability to initiate movement (akinesia), and increased muscle tone (rigidity). The akinetic-rigid disorders are exemplified by Parkinson's disease and other causes of parkinsonism. Although parkinsonism refers to an akinetic-rigid syndrome, hyperkinetic phenomena, such as a tremor, may be concurrent and remain classified as hyperkinetic movements in that context.

Acute Medication-Induced Movement Disorders

Acute Dystonia and Acute Dystonic Reactions

Presentation

Acute dystonic reactions involve abnormal muscle contractions (increased muscle tone) and postures that result in sustained involuntary twisting or repetitive patterned movements. The body regions most often affected are ocular muscles (oculogyric crisis or blepharospasm) or face, jaw, tongue, or neck muscles (torticollis or retrocollis), and, less often, the trunk or limbs (limb dystonia). The sustained muscle contractions cause pain, discomfort, and anxiety. Presentation varies according to the affected muscle group (e.g., trismus; a thickened, tense tongue or throat; dystonic mouth opening; grimacing; dysarthria; swallowing difficulties; unusual neck turning, limb postures, or truncal twisting). A few fingers may be the only affected body part, or the dystonia may be generalized, as with opisthotonos. Because presentations of acute dystonia are protean and can be bizarre, an episode can be mistaken for a functional movement disorder.

Most acute dystonic reactions occur soon after initiating treatment, typically following a single dose or an increase in the dosage of an offending agent. The onset can occur within a few minutes of ingestion but usually develops over a period ranging from a few hours to as long as 2-5 days after initiating or raising the dosage of the inciting medication or after reducing the dosage of a medication used to treat or prevent acute dystonia. In comparison with earlier symptom onset, emergence of dystonic phenomena after 10 days is more likely to represent tardive dystonia or another cause of dystonia. Other causes of dystonia should be considered if the acute dystonic reaction fails to respond to acute treatment, indicated below.

Acute laryngeal dystonia can result in life-threatening airway obstruction and requires emergency treatment. Its presentation involves stridor, clutching the throat, dysphonia, respiratory distress, and dysphagia. The population at greatest risk for acute dystonic reactions is young people--including infants, children, and adults who are younger than 40 years and have psychosis. Both genders are susceptible, but development of acute dystonia is more likely in adult males than females in most studies (van Harten *et al.* 1999). A history of acute dystonic reactions confers an increased risk for subsequent events, as does recent cocaine use, hypocalcemia, dehydration, or hypoparathyroidism. Acute dystonic reactions rarely develop in the elderly (van Harten *et al.* 1999).

Offending Medications

Any DRB medication can cause acute dystonia. The most common causes in a psychiatric population are antipsychotics. Observed rates are higher with FGAs (17% of patients treated with haloperidol) than with SGAs (< 2% of patients treated with quetiapine or clozapine) (Martino *et al.* 2018). Other psychiatric medications or drug classes reported as causing acute dystonic reactions include selective serotonin reuptake inhibitors (SSRIs), opioids, methylphenidate, rivastigmine, and gabapentin. Various other DRB medications (e.g., antiemetic, anti-infective, and antiepileptic agents) can also cause acute dystonia (see Table 36-1).

The mechanisms underlying acute dystonic reactions are unknown. The increased risk for acute dystonic reactions associated with high-potency DRB antipsychotics, the lower risk with lower-potency antipsychotics, and the prompt relief of acute dystonic reactions with anticholinergic medications all suggest a relationship between relative dopamine and cholinergic blockade.

Treatment

Acute dystonic reactions cause significant physical discomfort and distress that is often followed by anxiety about taking the offending medication and related medications in the future. Even with SGAs, there is always risk at the individual patient level. Clinicians should be vigilant for this potential complication to facilitate its prompt management and to avoid deleterious effects on medication adherence. Patients and families, especially those in high-risk groups, should be informed prior to starting a potentially offending agent of the risk for acute dystonic reactions and the need to monitor for and manage them. In general, once an acute dystonic reaction occurs, the offending medication is discontinued and a different agent, as indicated, is substituted. The offending drug should be avoided thereafter, as there is a risk for recurrent acute dystonic reactions.

Management of an acute dystonic reaction requires immediate intervention. In inpatient or emergency settings, intramuscular anticholinergic benztropine (1-2 mg) provides rapid relief of acute dystonic reactions, usually within 20 minutes. Second and third injections, administered every 30 minutes, may be needed. Given that parenteral benztropine has a short half-life, acute dystonic reactions can recur within several hours and require additional dosing. Acute treatment should be followed by a brief course of an oral anticholinergic drug for 4-7 days to prevent recurrence (Park *et al.* 2017). To prevent recurrent acute dystonic reactions, the prophylactic dosage should then be reduced gradually. Potential adverse effects of anticholinergics are detailed below.

Intravenous anticholinergic treatment is indicated when the dystonia is life-threatening (i.e., with laryngeal stridor, risk of joint dislocation). Clonazepam 0.5-4 mg may be indicated when oculogyric crisis fails to respond to anticholinergic medications.

Diphenhydramine (50-100 mg IM or IV) can be used emergently, although it is less effective than the immediate relief provided by benztropine (2 mg IM) (Lee 1979). Outpatients who experience acute dystonic reactions should be advised to self-administer oral diphenhydramine and seek further medical care. Benzodiazepines can also be considered but are less effective than anticholinergics. Botulinum toxin injections have been suggested for drug-induced stridor with laryngeal dystonia (Burkhard 2014) as well as for prophylaxis in patients subject to relapse of laryngeal dystonia (Marano *et al.* 2016).

Prophylactic Treatment of Acute Dystonic Reactions

When an antipsychotic medication is started or continued, acute dystonic reactions can be prevented by using anticholinergic drugs during the first 7 days of treatment

(Burkhard 2014). Based on the patient's compilation of risk factors (e.g., age, gender, antipsychotic potency, dosage), prophylactic anticholinergic medication (e.g., benztropine 2 mg two to three times daily) can be added to treatment with the antipsychotic medication. Amantadine 100 mg once to three times daily is used as an alternative when anticholinergics are not tolerated. As above, prophylactic treatment should be continued for 7 days and then tapered slowly to avoid inducing an acute dystonic reaction. High-potency antipsychotic drugs can be started at low dosages to reduce the risk of acute dystonic reactions (van Harten *et al.* 1999). Prolonged or routine use of prophylactic agents is discouraged (World Health Organization 1990).

Acute Akathisia

Presentation

The term *akathisia*, meaning "inability to sit," was first used by Ladislav Haskovec, a Czechoslovakian neuropsychiatrist (Brune and Sachdev 2002), in 1901 to describe psychomotor restlessness in unmedicated patients regarded as having "hysteria" or "neurasthenia" (Sachdev 1995). In 1960, akathisia, as a medication-induced condition, was reported in patients taking phenothiazine antipsychotics (Salem *et al.* 2017). While its association with antipsychotic medications is well recognized, akathisia also occurs as a side effect of numerous psychiatric and nonpsychiatric medications, including antidepressants, dopamine-blocking antiemetics, calcium channel blockers, and antiepileptic agents. For this reason, akathisia often goes unrecognized, especially in medical and geriatric settings where individuals are prescribed antipsychotic medications for agitation, delirium, or psychosis in the context of dementia (Forcen *et al.* 2016) or in oncology, neurology, or primary care settings (Akagi and Kumar 2002; Rissardo *et al.* 2021). It is also important to distinguish akathisia from restless legs syndrome. The latter generally manifests during times of rest or sleep and is treated with dopamine agonists, which could exacerbate psychosis and lead to higher dosages of antipsychotics and worse akathisia (Bratti *et al.* 2007). Any acute onset of restlessness and agitation should prompt consideration of akathisia and a review of medications for the recent initiation or dosage increase of drugs or prescribing cascades known to cause akathisia.

Unlike the other common medication-induced movement disorders, akathisia has prominent subjective and objective components. Typically, there is a complaint of a mounting or excessive internal restlessness or tension that is accompanied by a strong urge to move around, such as when sitting in a class or standing in a line (Pringsheim *et al.* 2018). The experience of akathisia can be entirely subjective, without observed abnormal movements. However, for many patients, movement provides some relief of their symptoms.

The types of movements constituting akathisia vary across individuals; manifestations of akathisia can include inability to sit, stand, or lie still and usually (although not exclusively) involves the legs. Movements include pacing, leg swinging or crossing, marching in place, shifting from one foot to the other, shaking, rocking the legs or trunk back and forth, rubbing the face, fidgeting, scratching, or moaning. The movements tend to be bilateral and symmetrical. Pseudoakathisia, a debated entity classified as a form of chronic akathisia (Havaki-Kontaxaki *et al.* 2000), involves objective signs of akathisia in the absence of awareness of internal restlessness.

One challenge in diagnosing akathisia is that some patients, both adults and children, are unable to find words to describe their symptoms (Akagi and Kumar 2002). Vague and nonspecific complaints of inner tension, anxiety, an inability to relax, nervousness, restlessness, discomfort, and so forth, accompanied by irritability, agitation, and constant motion, may be misattributed to a primary psychiatric condition or a new onset of a mood or psychotic disorder. In the context of failure to recognize a medication-induced disorder, offending medications (e.g., antipsychotics, antidepressants) might be initiated or increased, thereby further exacerbating the akathisia symptoms (Pringsheim *et al.* 2018). The physical experience of inner restlessness often gives rise to emotional distress, anxiety, or dysphoria; acute, severe, or chronic cases of akathisia can lead to self-harm, suicidality, aggression, or violence. Distress associated with akathisia also contributes to medication nonadherence.

Onset of acute akathisia is typically rapid, with symptoms usually appearing within a few days to a week of starting--or increasing the dosage of--the offending medication. In published diagnostic criteria for akathisia (Bratti *et al.* 2007), acute akathisia requires symptom onset within 6 weeks of drug initiation or dosage increase (plus the absence of reduction or discontinuation of a therapeutic agent within the 2 weeks before symptom onset). For the diagnosis of chronic akathisia with acute onset, symptoms must have persisted for more than 3 months. For tardive akathisia (discussed further in the later section "Tardive Dyskinesia and Tardive Syndromes"), symptom onset must have occurred at least 3 months after starting an antipsychotic agent; the diagnosis also requires the absence of a change in antipsychotic dosage or medication within 6 weeks before symptom onset and the absence of a reduction or discontinuation of another therapeutic agent in the 2 weeks before symptom onset. First-time use of an antipsychotic and a rapid increase in antipsychotic dosage appear to confer greater risk for akathisia than does simply taking a higher dosage of an offending agent. Other than rare reports of clozapine-induced akathisia, which is more likely to occur in children and adolescents than in adults (Gogtay and Rapoport 2008; Grover and Sahoo 2015), there is no apparent impact of age or sex on the prevalence of antipsychotic-induced akathisia (Laoutidis and Luckhaus 2014).

Offending Medications

Akathisia is most prevalent as an adverse effect of treatment with an antipsychotic, particularly a high-potency FGA (e.g., haloperidol, fluphenazine). In community-based samples, the overall prevalence of akathisia in individuals with schizophrenia is around 20% (Pringsheim *et al.* 2017). Meta-analyses show a lower prevalence of akathisia with intermediate-and low-potency FGAs. Certain SGAs (e.g., aripiprazole, asenapine, paliperidone, ziprasidone) are associated with higher rates of akathisia (Forcen *et al.* 2016). Akathisia risk is also higher for patients receiving two different SGAs than for those receiving an SGA plus an FGA. Compared with SGA monotherapy, SGA polytherapy confers a threefold higher risk of akathisia (10.9% vs. 34.2%) (Salem *et al.* 2017). Akathisia can also occur with clozapine and (as noted earlier) appears to have a relatively greater incidence in children than in adults (Gogtay and Rapoport

2008; Gogtay *et al.* 2002). Lithium-induced akathisia is also described (Demir *et al.* 2021).

Table 36-1 lists psychiatric and nonpsychiatric medications that are also reported to cause akathisia. Akathisia should be distinguished from psychomotor activity related to anxiety, agitation, tics, classic TD, or restless legs syndrome (Salem *et al.* 2017).

Treatment

The first principles in management of akathisia are risk mitigation strategies and monitoring for its potential occurrence. Patients and caregivers should be informed that akathisia is a potential medication-induced side effect and should be educated about its features. These should be distinguished from phenomena associated with the primary psychiatric condition or distress that arises in the context of a primary medical condition. The contribution of a drug-induced akathisia to the clinical picture is worthy of consideration on medical units, where restlessness, distress, and anxiety might be misattributed to delirium or existential concerns (e.g., in a patient with dementia or after a diagnosis of cancer). A best practice is to use a validated scale to assess patients for signs and symptoms before starting and while titrating the dosage of a potentially offending agent. The Barnes Akathisia Rating Scale has established reliability, validity, and utility for this purpose (Pringsheim *et al.* 2017). When prescribing antipsychotics, polypharmacy, rapid dosage escalation, and high-dosage treatment should be avoided when there is no evidence for clinical effectiveness, even if there is no obvious clinical harm.

Once evidence for akathisia is established, offending medications should be tapered and, if clinically appropriate, discontinued or substituted with an alternate medication or other treatment approach. When long-term use of the offending medication class is necessary, efforts should be made to taper and discontinue the specific medication, and, if the patient is already on monotherapy, switch, if possible, to an agent with an overall lower risk profile for akathisia, such as clozapine, olanzapine, or quetiapine in the case of antipsychotic treatment (Pringsheim *et al.* 2017). Clozapine should be considered for intractable or refractory akathisia (Salem *et al.* 2017).

Clinical trials of anti-akathisia medications have focused mainly on use of b-blockers and are limited to individuals taking antipsychotic medications (Pringsheim *et al.* 2018). A systematic review on treatment of antipsychotic-induced akathisia reported on seven published placebo-controlled trials evaluating propranolol, a nonselective b-adrenergic receptor antagonist (Pringsheim *et al.* 2018). For children and adults with antipsychotic-induced akathisia, propranolol is generally the first-line treatment barring individual medical contraindications or precautions regarding its use (e.g., asthma, orthostatic hypotension, bradycardia, drug-drug interactions).

A prudent starting dosage for propranolol is 5-10 mg two to three times a day with titration as needed for symptomatic improvement. Relative to placebo in controlled trials involving patients with schizophrenia, propranolol showed greater efficacy at dosages ranging from 20 mg/day to 120 mg/day. Both nonselective (b_1 and b_2 antagonism) and selective (b_1 antagonism) b-blockers are also reported to be efficacious. For once-daily dosing, the usual starting dosage of b_1-selective atenolol is 50 mg/day. Betaxolol may be the b-blocker of choice for patients with lung disease and smokers because of its b_1 selectivity at lower dosages (5-10 mg/day). Limited data support use of clonidine, a selective a_3-adrenergic agonist, up to 0.15 mg/day, as an alternative option for akathisia, although its associated side effects of sedation and hypotension can be problematic (Fleischhacker *et al.* 1990).

More recently, postsynaptic serotonin 5-HT_{2A} receptor antagonists (e.g., ritanserin, cyproheptadine, trazodone, mianserin, mirtazapine) have entered the armamentarium of potential anti-akathisia agents (Poyurovsky and Weizman 2020). The most robust evidence supports use of mirtazapine 7.5-15.0 mg once daily as a long-term anti-akathisia treatment when propranolol is contraindicated, not effective, or not tolerated (Pringsheim *et al.* 2018). A meta-analysis of data from placebo-controlled trials of mianserin, mirtazapine, and trazodone showed a positive effect for all three 5-HT_{2A} antagonists as a group (RR = 7.10, 95% CI = 3.08-16.40; $P < 0.0001$) (Laoutidis and Luckhaus 2014). However, mirtazapine showed a more favorable safety and side-effect profile (sedation, weight gain) when used with antipsychotics, in contrast to mianserin (15 mg/day) and trazodone (100 mg/day), which have adrenergic-blocking properties. Cyproheptadine 8-16 mg/day is an alternative option, although trial data are limited.

Several other agents have been evaluated or suggested as anti-akathisia agents. Two small short-term trials of oral vitamin B_6 600 mg/day or 1,200 mg/day versus placebo showed significant anti-akathisia effects. Short-term use (5 days) can be considered; long-term administration (> 12 months) of oral vitamin B_6 at dosages of 1,000 mg/day can result in a sensory neuropathy and is not recommended (Pringsheim *et al.* 2018). The antihistamine diphenhydramine, which also has potent anticholinergic properties, has not shown any consistent benefit for this indication and may worsen akathisia (Salem *et al.* 2017). Insufficient data support use of other medications evaluated as potential akathisia treatments. Dopamine agonists have limited utility, given their propensity to increase psychosis. An earlier study of amantadine suggested that it is probably not effective for treating akathisia (Fleischhacker *et al.* 1990). However, because a small number of patients have shown beneficial effects, amantadine 100 mg/day is recommended as a final option only after other interventions have failed (Poyurovsky 2010). Gabapentin and pregabalin, which can be effective for restless legs syndrome, are cited in case reports as benefiting as well as inducing akathisia, although these agents may improve tardive akathisia (Pringsheim *et al.* 2018; Salem *et al.* 2017). Sodium valproate showed no significant effect on akathisia and also increased parkinsonism (Friis *et al.* 1983).

Anticholinergics are not recommended as a treatment for akathisia, given their unfavorable effects on cognition, other adverse effects, and limited and inconsistent evidence for efficacy (Rathbone and Soares-Weiser 2006). For example, a small placebo-controlled trial of parenteral benztropine showed improvement in subjective symptoms of akathisia, but not in objective signs (Sachdev and Lonergan 1993). In a trial comparing an unusually high dosage of oral benztropine (6 mg/day) and propranolol (80 mg/day) against placebo, both drugs produced significant improvement in akathisia ratings relative to placebo (Adler *et al.* 1993a). In an earlier comparison trial, however, propranolol was more effective for antipsychotic-induced akathisia than was benztropine (up to 4 mg/day), which yielded a slight decrease in subjective akathisia ratings but no change in objective ratings (Adler *et al.* 1987). Observational reports suggest that anticholinergics may benefit individuals with both parkinsonism and akathisia, but cautious use is advised (Braude *et al.* 1983). A single case report described temporary resolution and diminution of all motor abnormalities after a course of electroconvulsive therapy (ECT) in a patient with antipsychotic-induced akathisia and parkinsonism that was not responsive to anticholinergic medications (Hermesh *et al.* 1992). Conversely, there are reports of worsening akathisia with ECT (Bakheit 1997).

Benzodiazepine agents do not reduce akathisia and are not recommended as a specific treatment. They may be indicated in the short term for severe anxiety or agitation

in patients also treated with propranolol. Oversedation is a significant risk when benzodiazepines are co-administered with mirtazapine, mianserin, or cyproheptadine.

Acute Medication-Induced Nonparkinsonian Tremor

Presentation

Drug-induced tremors can be vexing to diagnose. Some psychiatric medications, such as lithium and valproate, cause parkinsonism as well as nonparkinsonian tremors. Nonparkinsonian drug-induced tremors tend to resemble essential tremor and most often manifest as an enhanced physiological tremor that is lower amplitude (i.e., finer), faster (i.e., with higher-frequency oscillations [10 cycles per second]), affects both upper limbs, and emerges when maintaining a position against gravity (postural tremor), during voluntary movement (kinetic tremor), or both. A nonparkinsonian drug-induced tremor is most likely to be evident during intentional postures, such as when writing or holding a coffee cup. Usually, physiological tremors are not symptomatic or visible, except when enhanced by fatigue, anxiety, or an offending drug (Bhatia *et al.* 2018).

Drug-induced tremors are typically isolated tremor syndromes (i.e., tremor is the only abnormal sign), although other medical or neurological conditions may co-occur. The clinical history, tremor phenomena and other signs on exam, and further testing, as indicated, help distinguish a drug-induced tremor from other causes of tremor. As would be expected, acute drug-induced tremors are more likely to demonstrate a temporal relationship between drug ingestion and tremor onset, a dose-response relationship, absence of tremor progression, and normalization of enhanced tremor upon removal of the offending drug. Other etiologies of tremor should be excluded, such as Parkinson's disease, essential tremor, hyperglycemia, hyperthyroidism, cerebellar disease, or cerebral vascular lesions.

Drug-induced tremors begin soon after ingestion of the drug, after dosage escalation, or via drug-drug interactions when a new drug is added to an existing regimen. Other triggering factors for enhanced physiological tremor in the context of an offending drug include polypharmacy, caffeine use, metabolic conditions, anxiety or mood states, alcohol withdrawal, fever, or shivering when the ambient temperature is low (Factor *et al.* 2019).

Offending Medications

Nonparkinsonian tremor is a common side effect of many drugs (Baizabal-Carvallo and Morgan 2022). Common tremor-inducing psychiatric drugs include antidepressants, notably SSRIs and tricyclic antidepressants (TCAs), lithium, antiepileptics (especially valproate), bronchodilators, amiodarone, and immunosuppressants. A recent review of 97 patients with drug-induced movement disorders in a neurology practice found that postural hand tremor was the most common movement disorder in those exposed to non-DRB drugs (54%), especially antiepileptics and antidepressants. However, postural tremors were also present in the groups on only DRB agents (17%) and on both DRB and non-DRB drugs (40%) (Chouksey and Pandey 2020).

Lithium-induced nonparkinsonian tremor occurs in about 30% of patients, is more common in older individuals and men, and is reported as problematic by about one-third of patients who experience it. A lithium-induced tremor usually presents early in the course of treatment, necessitating consideration of other causes of tremor when the onset is later (Gitlin 2016). Although the tremor may improve over time with stable therapy, addition of other psychiatric drugs (e.g., SSRIs, TCAs, valproate) can exacerbate the movements. Lithium toxicity can also exacerbate these movements, causing the tremor to become more coarse, irregular, and severe, spreading to other body parts and accompanied by other signs of toxicity. Coadministration of DRB antipsychotics with lithium can result in a complex combined tremor syndrome of multiple etiologies. Lithium is also associated with drug-induced parkinsonism, akathisia, chorea, myoclonus, a cerebellar syndrome, and serotonin syndrome (Meneret *et al.* 2021). Coadministration of carbamazepine with lithium, such as when both are used as mood stabilizers, increases the risk for ataxia and hyperkinetic movements such as myoclonus or dystonia.

Valproate, like lithium, is frequently associated with a parkinsonian or a nonparkinsonian tremor (Meneret *et al.* 2021). Nonparkinsonian valproate-induced tremor is categorized as a form of enhanced physiological tremor. It affects up to 80% of patients taking valproate. Although this tremor is usually mild, nearly 25% of affected patients (who tend to be relatively older and female) have more severe tremor that causes significant functional impairment (Alonzo-Juarez *et al.* 2017). Because the tremor tends to be bilateral and symmetric, and to involve the upper extremities, it frequently resembles essential tremor, one of the most common idiopathic movement disorders (Alonso-Juarez and Baizabal-Carvallo 2018). By contrast, however, tremor occurrence tends to be dosage-related and associated with a longer duration of valproate treatment (Zhang *et al.* 2020). Some studies have reported that higher tremor amplitude is seen with immediate-release formulations than with controlled-release formulations of valproate, although these data are controversial (Baizabal-Carvallo and Morgan 2022). Valproate-induced tremor is also reported to present as a tardive tremor.

Treatment

The cornerstone of effective management is proactive clinical and functional assessment. Patients should be assessed for preexisting tremor, including an enhanced physiological tremor, and educated about the potential for drug-induced tremor prior to initiating medications known to induce tremor (Baizabal-Carvallo and Morgan 2022). In the absence of baseline and serial exams, causes other than drug-induced tremor must be considered. Interventions for a drug-induced tremor include dosage alterations and reductions, elimination of additive factors such as caffeine, cessation of the offending drug if feasible, or transition to an alternative agent. For most patients, the nonparkinsonian tremor improves with time and is not disabling. More severe or socially embarrassing tremors can warrant medications for management, but watchful waiting for a natural diminution of symptoms and management of triggers are important first steps to avoid polypharmacy and deleterious prescribing cascades.

When medication treatment is necessary, b-blockers are used most often for a nonparkinsonian drug-induced tremor. Although the recommended dosage range for treatment of tremor with propranolol is 20-320 mg/day, a dosage less than or equal to 120 mg/day is usually effective (Gitlin 2016). Case reports describe use of primidone

and vitamin B_6. Benzodiazepines may be used when anxiety contributes significantly to the tremor.

Subacute Medication-Induced Movement Disorders

Medication-Induced Parkinsonism

DIP, the second most common cause of parkinsonism after idiopathic Parkinson's disease in general population studies, is a significant source of morbidity. Severe antipsychotic DIP occurs with both FGAs and SGAs, contributes to nonadherence, and can lead to complete immobility, dysarthria, and dysphagia as well as secondary complications such as falls with injuries and pneumonia (Druschky *et al.* 2020). Older individuals with DIP have higher rates of falls, hospitalizations, and mortality than do younger persons (Wilson and MacLennan 1989). Given that early recognition is important, any new case of parkinsonism should prompt a thorough medication history. However, the true prevalence of DIP is unknown, as it is underrecognized, and epidemiological studies tend to include all types of parkinsonism without distinguishing DIP cases (Thanvi and Treadwell 2009). In a population-based study of 706 men and women ages 50-89 years in northern Italy, comprehensive diagnostic assessments by movement disorder specialists identified a high overall prevalence (*n* = 214 participants, 28.0% [95% CI 25.9-30.1]) of common movement disorders, including parkinsonism, tremor, dystonia, chorea, tics, and restless legs syndrome (Wenning *et al.* 2005). Among the 214 participants with movement disorders, 43 cases (20%) were regarded as drug-induced, yielding a DIP prevalence of 1.69% (1.06%-2.33%). In the group of 33 individuals taking long-term (> 6 months) antipsychotic treatment in the 5 years before study assessment, 16 (49%) developed movement disorders (7 with DIP, 5 with DIP plus dystonia, and 4 with dystonia) (Wenning *et al.* 2005).

Globally, more than half of individuals older than 60 years taking long-term antipsychotics are estimated to have DIP (Estevez-Fraga *et al.* 2018). Studies suggest that DIP may be present in up to 12% of community populations, with a higher incidence in older age groups (Savica *et al.* 2017; Wisidagama *et al.* 2021). In a 30-year (1976-2005) population-based study in Olmsted County, Minnesota, 108 individuals, among the 906 incident cases of parkinsonism, developed DIP in association with prescription of DRB or dopamine-depleting agents (Savica *et al.* 2017). This finding corresponds to an average annual incidence rate (age-and sex-standardized to the total 1990 population) of 3.8 per 100,000 person years for DIP relative to a rate of 33.5 for all types of parkinsonism. The prevalence and natural course of DIP in individuals with continued drug exposure are not known. Severe, chronic DIP appears to be uncommon. With ongoing antipsychotic treatment, DIP may resolve spontaneously, but in up to half of patients it persists or progresses over time (Fernandez *et al.* 2001).

Presentation

Parkinsonism is defined by the presence of at least two of the three cardinal motor features of Parkinson's disease--bradykinesia (including akinesia), tremor, and rigidity. Other features include postural instability, abnormal flexed or stooped posture, micrographia, and hypophonia. On cross-sectional exam, clinical characteristics of

DIP are phenomenologically indistinguishable from the akinetic-rigid syndrome of idiopathic Parkinson's disease. Even asymmetric motor signs, a defining feature of idiopathic Parkinson's disease, may be present in DIP. Bradykinesia and akinesia result in decreased or absent facial movements (*hypomimia*, or "masked face"), a reduced blink rate leading to a staring appearance, and a reduced rate of swallowing, which causes drooling because of pooling of saliva. Gait abnormalities include shortened stride with a normal or narrow base, reduced or absent arm swing, stooped posture, a shuffling and festinating gait, and *en bloc* turning. Rigidity is experienced as involuntary stiffness and inflexibility of the muscles of the limbs, shoulders, neck, or trunk. On examination, increased muscle tone is constant throughout range of motion ("lead-pipe" rigidity) when the limb is moved passively around the joint.

Tremor associated with DIP most often occurs in the resting state and with sustained postures. Typically, fingers or hands are involved, but the tongue, jaw, or feet can be affected. The tremor ranges from mild to severe and can interfere with daily functions. Although a resting tremor resolves with movement, reemergence of the tremor when movement is halted (e.g., when a hand holding a soup spoon stops to deliver food to the mouth) can be debilitating. The classic parkinsonian "pill-rolling" tremor, a finger tremor in which the thumb and fingers move as if rolling a pill back and forth, is considered uncommon in DIP. However, because a pill-rolling tremor may occur intermittently in DIP, its absence on exam is not a firm basis for distinguishing Parkinson's disease from DIP (Shuaib *et al.* 2016). *Rabbit syndrome*, a variant of DIP, is characterized by a rapid tremor of the lips and perioral area that resembles the rapid chewing-type movements of a rabbit's mouth (Villeneuve 1972).

The time course for developing DIP varies, but time of onset after drug exposure is usually later than for acute drug-induced akathisia or dystonia (Ayd 1961). For this reason, diagnosis of DIP is typically supported by a subacute onset over the days to weeks after starting the offending drug or increasing its dosage, or after reducing the dosage of an antiparkinsonian medication used to treat DIP or acute drug-induced dystonia. This temporal relationship between medication initiation and motor symptom onset should be evident, along with absence of symptoms prior to initiation of treatment with the drug and resolution of symptoms within 6 months after drug discontinuation (Wisidagama *et al.* 2021). Drug dosage influences the timing of DIP onset (Levinson *et al.* 1990), and overall risk varies across the antipsychotics and other agents causing DIP. Most antipsychotic (or anti-dopaminergic) DIP emerges in 1-3 weeks, and 90% of cases are evident by 3 months (Ayd 1961; Freyhan 1959; Medina *et al.* 1962). DIP can also develop insidiously; for example, DIP secondary to calcium channel blockers may not arise until after 9-12 months of treatment (Bondon-Guitton *et al.* 2011; Llau *et al.* 1994; Thanvi and Treadwell 2009).

Discontinuation of the causal agent is expected to result in resolution of DIP, but the clinical course may not be straightforward. Differentiating DIP from idiopathic Parkinson's disease is especially challenging in older individuals who have been maintained on long-term, stable medications that are known to cause DIP. At issue is whether the medication "unmasks" Parkinson's disease or whether older age renders a patient more sensitive to the medication's effects. In either case, stopping the medication reduces parkinsonism, although complete resolution of DIP may take more than a year. When underlying Parkinson's disease neuropathology is present, parkinsonism will eventually resume and progress. A Canadian autopsy series found that

DRB antipsychotics can unmask preclinical Parkinson's disease, as demonstrated by cases with insufficient substantia nigra degeneration to manifest Parkinson's disease clinically once the offending drug was removed (Shuaib *et al.* 2016). Of etiological interest, the autopsy series did not find neuropathological evidence for neurotoxicity or nigral degeneration secondary to the effects of DRB antipsychotics (Shuaib *et al.* 2016).

Given that management and prognosis of DIP and Parkinson's disease differ, dopamine transporter (DAT) single-photon emission computed tomography (SPECT) scanning can be used to distinguish DIP from Parkinson's disease. In antipsychotic-induced DIP, there is postsynaptic D_2 receptor blockade, and DAT-SPECT nigrostriatal binding is expected to be normal; in Parkinson's disease, presynaptic nigrostriatal dysfunction results in reduced DAT-SPECT binding (Tinazzi *et al.* 2014).

Risk Factors

Identification of discrete risk factors for DIP is confounded by individual variations in drug dosage and exposure duration that confer susceptibility. Both DRB agents and dopamine-depleting agents are known to cause DIP, whereas the mechanisms underlying DIP associated with calcium channel blockers, gastrointestinal prokinetics, antidepressants, and antiarrhythmics are not fully understood (Lopez-Sendon *et al.* 2013). High drug potency, higher dosages, and longer exposure are clear drug-related risk factors for DIP. Older age, female sex, dementia, severe psychiatric disease, brain damage, idiopathic Parkinson's disease, hypertension, HIV infection, and preexisting evidence for drug-induced movements are regarded as possible risk factors (Wisidagama *et al.* 2021).

Offending Medications

Both DRB and non-DRB medications (see Table 36-1) are associated with DIP. With the greater focus on DRB antipsychotics as causal in DIP, the potential role of non-DRB psychiatric medications--such as antiepileptics or mood stabilizers, calcium channel blockers, gastrointestinal prokinetics, and antiarrhthymics--can be overlooked. Notably, antiepileptic medications, used to treat primary psychiatric conditions, chronic pain, or seizures, are a significant cause of DIP and other drug-induced movement disorders, including in individuals with epilepsy (Zaccara *et al.* 2004; Zhou *et al.* 2022).

Both valproate and lithium are recognized independent causes of DIP in the absence of antipsychotic exposure. Although mechanisms of valproate-induced and lithium-induced DIP are not known, a recent review of patients undergoing DAT-SPECT scanning found that, after antipsychotics, valproate and lithium were the most suspected causative agents of DIP. The diagnosis of DIP was supported by normal DAT scans in 8 of 9 patients taking lithium and in 11 of 17 patients taking valproate and resolution of symptoms after drug cessation (Friedman 2020; Yomtoob *et al.* 2018).

The prevalence of valproate-induced DIP is typically reported as less than 10%, although reported estimates range from 1.4% to 75% (Brugger *et al.* 2016). Rates of nonparkinsonian tremor caused by valproate are higher (Armon *et al.* 1996). DIP can occur with exposure to lithium only, but risk may be greater in patients receiving both lithium and an antipsychotic (Ghadirian *et al.* 1996). Case reports and small series also describe DIP secondary to antidepressants, particularly SSRIs, although trazodone and tricyclic agents in psychiatric and nonpsychiatric settings are also implicated (Gerber and Lynd 1998; Leo 1996). Mechanisms for SSRI-induced DIP are also unclear. Potential causes include serotonergic inhibition of dopamine or the effects of other drugs combined with an SSRI.

Prevention

Management of DIP starts with prevention. Clinical examination for evidence of parkinsonism and other abnormal movements should be conducted *before* starting any medication known to have this iatrogenic effect. This examination should be followed by efforts to use the lowest effective dosage of medication and to gradually raise the dosage with frequent monitoring for signs of parkinsonism in an ongoing manner, especially during the first 3 months of treatment. The Simpson-Angus Scale (SAS) is a standardized tool that is commonly used to evaluate DIP in clinical trials, despite the fact that only 7 of its 9 items assess rigidity signs and none assess tremor, bradykinesia, or postural instability (Friedman *et al.* 2005; Simpson *et al.* 1964). When the SAS is used to monitor DIP, the additional signs and their functional impact warrant initial and serial assessment, especially in older individuals or those with other risk factors for DIP (e.g., brain injury, drug-drug interactions). Systematic monitoring is also important because of the subacute nature of DIP, the variability in its onset, and the possibility that DIP signs may resolve spontaneously while the patient is still taking the offending antipsychotic (Marsden and Jenner 1980).

Treatment

Once DIP emerges and is symptomatic, initial management is to reduce the offending agent to the lowest clinically effective dosage and continue to monitor parkinsonian symptoms and signs for at least 6 months. At lower medication dosages, milder symptoms of DIP may not require any interventions. When possible, the offending drug should be stopped, although it may not be possible to discontinue medications without worsening psychiatric symptoms. Transition to a medication with a lower propensity for DIP is then indicated. Among antipsychotics, transition may involve switching or cross-titrating from an FGA to an SGA. Quetiapine and clozapine are the only commonly available SGAs that do not worsen parkinsonism. Pimavanserin, a selective inverse agonist at 5-HT_{2A} indicated for psychosis in Parkinson's disease, also does not cause parkinsonism. Currently, its use is restricted to patients with Parkinson's disease. When those medications are not feasible, an antipsychotic with increased anticholinergic effects, such as chlorpromazine or olanzapine, can be used.

When antipsychotic treatment is initiated with risks of DIP (plus acute motor side effects) in mind, many patients will not require adjunctive antiparkinsonian medications to manage DIP. The practice of prescribing antiparkinsonian medications, usually anticholinergics, to prevent effects of DIP on medication adherence is discouraged, even in younger patients.

Even in acute psychiatric settings, use of higher starting dosages of antipsychotics that then require acute use of antiparkinsonian medications can be counterproductive. An alternative strategy (Miller 1997) is to titrate the antipsychotic dosage to the "neuroleptic threshold" (i.e., the point of minimal hypokinesia or rigidity [Haase 1965]) and then use other medications, such as benzodiazepines, to manage agitation. During maintenance antipsychotic treatment, emergent DIP should be managed initially with attempts to reduce the antipsychotic dosage before adding an anticholinergic medication. Select situations (e.g., younger patients susceptible to acute dystonia) warrant additional monitoring and education before initiating antiparkinsonian therapy.

When dosage reductions or an alternate medication fails to resolve DIP or these strategies are not feasible, antiparkinsonian medications used to treat idiopathic Parkinson's disease are also used for DIP. Research on their efficacy is limited, as is research on their reported effects on DIP (Friedman 2014). For anticholinergics and amantadine, efficacy data are similar, but amantadine has a safer adverse-effect profile and, anecdotally, is recommended by movement disorder specialists for initial use (Fann and Lake 1976; Magnus 1980; Mamo *et al.* 1999). Yet, current prescribing practices remain influenced by the early open-label observations suggesting effectiveness of anticholinergic agents for DIP (Medina *et al.* 1962; Rashkis and Smarr 1957). For this reason, anticholinergic agents--namely, trihexyphenidyl, benztropine, and diphenhydramine (an antihistamine with anticholinergic properties)--remain the mainstays of treatment for DIP. Their actual efficacy is thought to be overestimated, as subsequent controlled trials primarily compared different anticholinergics, did not include placebo arms, or showed limited evidence for their efficacy over placebo (Wisidagama *et al.* 2021). Symptomatic but inconsistent benefit was also reported with L-dopa (Hardie and Lees 1988). Selegiline, a selective and irreversible monoamine oxidase (MAO) type B inhibitor used to treat Parkinson's disease, has also been used for DIP (Gewirtz *et al.* 1993). A single trial of propranolol for DIP showed no benefit relative to placebo (Metzer *et al.* 1993).

Amantadine for DIP has been investigated more extensively compared with anticholinergic agents, the data demonstrating its efficacy are less conflicting, and its safety profile, while not benign, is better tolerated in the elderly (Friedman *et al.* 2005; Mamo *et al.* 1999). Most clinical trials reported amantadine as equal in efficacy to benztropine or biperiden (not currently available in the United States) for DIP (DiMascio *et al.* 1976; Fann and Lake 1976; Konig *et al.* 1996; Silver *et al.* 1995; Stenson *et al.* 1976). Some studies reported amantadine as more effective than benztropine (Merrick and Schmitt 1973) or effective for DIP that is refractory to benztropine (Gelenberg 1978). Other studies reported amantadine as inferior to benztropine (Kelly *et al.* 1974), no more effective than placebo (Mindham *et al.* 1972), or unable to reduce antipsychotic-induced movements when used to replace an anticholinergic agent (McEvoy *et al.* 1987). These varying results can be attributed to differing methodologies and patient populations.

Based on these studies, amantadine 100-300 mg/day is regarded as effective for DIP. In patients with Parkinson's disease, amantadine appears to lose efficacy after several weeks (Mawdsley *et al.* 1972; Schwab *et al.* 1972). Most study durations were short, and there are no studies reporting on long-term efficacy of amantadine for DIP. Notably, there are no data supporting use of amantadine prior to initiating an anticholinergic for DIP.

Benztropine 1-8 mg as a total daily dosage is used to treat DIP. The maximum therapeutic response occurs in 3-10 days and response may take longer with more severe DIP (Fann and Lake 1976; DiMascio *et al.* 1976). The anticholinergic dosage can be increased until DIP is alleviated or the degree of anticholinergic side effects is unacceptable. There is no substantive difference in the reported efficacy of benztropine versus trihexyphenidyl.

When DIP remains uncontrolled on benztropine, a common practice is to add amantadine or substitute it as a single agent. A next step is often the addition of a benzodiazepine or a b-blocker, although there are few data to support either as a treatment. With severe DIP, a risk factor for NMS

(Levinson and Simpson 1986), the antipsychotic should be stopped temporarily.

Diphenhydramine is used to treat parkinsonism, including DIP in the elderly and mild cases of parkinsonism in other age groups. It is less effective than anticholinergics and carries risks for adverse effects (sedation, confusion) that affect older patients, but may be better tolerated in patients bothered by anticholinergic side effects. Diphenhydramine tends to be more sedating than anticholinergics, which may benefit some patients. Dosages generally range from 50 to 400 mg/day, given in divided doses.

Data supporting use of levodopa or dopamine agonists for DIP are limited. Usually, they are ineffective for DIP and may worsen psychosis or cause confusion (Friedman *et al.* 2005). For this reason, levodopa is not recommended as a treatment for typical DIP, although there may be specific instances in which a trial is indicated (e.g., severe, disabling DIP in younger individuals). Studies evaluating valproate or lithium DIP indicate occasional benefits from levodopa or dopaminergic drugs (Factor *et al.* 2019; Zhou *et al.* 2022). An analysis of Canadian health care data showed increased rates of dopaminergic drug prescribing among more than 1,700 patients age 65 years and older on lithium monotherapy, as compared to patients on antidepressants, suggesting that DIP is underrecognized and subject to a prescribing cascade associated with diagnosis of idiopathic Parkinson's disease (Marras *et al.* 2016).

Electroconvulsive therapy (ECT) is recognized as an effective treatment for both depression and motor symptoms in Parkinson's disease (Borisovskaya *et al.* 2016). Case reports describe similar benefits for DIP in patients receiving ECT for other psychiatric indications, but randomized clinical trials have not been conducted (Baez and Avery 2011; Goswami *et al.* 1989; Mukherjee and Debsikdar 1994; Sadananda *et al.* 2013). For individuals with depression or psychosis and DIP that cannot be managed with medication adjustments or adjunctive medications, ECT may be an effective option (Wisidagama *et al.* 2021).

Anticholinergic Prophylaxis Against Drug-Induced Parkinsonism

The controversy over anticholinergic prophylaxis stems from prospective and retrospective studies showing reduced rates of antipsychotic DIP when anticholinergics were prescribed prophylactically, but also showing that DIP developed in prophylactically treated patients (Friedman 2014; Friedman *et al.* 2005; Mamo *et al.* 1999). Further concerns are data showing that anticholinergics reduced the effects of antipsychotics on positive symptoms (Johnstone *et al.* 1983) and increased the risk of TD (Hyde *et al.* 2005). Accordingly, routine prescription of anticholinergic medications to counter potential DIP in patients receiving antipsychotics is not recommended, nor is indefinite use of such medications once they are prescribed (Friedman 2014; Mamo *et al.* 1999; World Health Organization 1990). Use of anticholinergic medications is contraindicated in elderly individuals, because the risks carried by these agents--memory loss, confusion, blurred vision, urinary retention, glaucoma exacerbation, and dry mouth--are greater than their potential benefits. For selected patients, especially younger individuals, the risk-benefit assessment may warrant anticholinergic prophylaxis, but generally anticholinergics are used only after parkinsonism is known to have developed and other measures (dosage reduction and switching to an alternative medication) have been ineffective. Once stable status on an antipsychotic medication is achieved, slow withdrawal of the anticholinergic medication should be attempted. The slow taper avoids an acute anticholinergic withdrawal syndrome and chronic, indefinite anticholinergic use in the absence of actual benefits.

Tardive Dyskinesia and Tardive Syndromes

In addition to ascertaining whether there has been any DRB medication exposure, awareness of tardive syndrome nosology is important for accurate diagnosis and treatment planning; individuals can have more than one tardive subtype superimposed on nontardive movement disorders. Treatment approaches and prognoses differ for each movement disorder subtype, and accurate diagnosis of tardive versus nontardive DRB medication-induced movement disorders is especially critical. Notably, discontinuation or dosage reduction of the offending DRB medication causes a tardive syndrome to emerge, persist, or worsen, but causes a nontardive DRB medication-induced movement disorder to improve or resolve.

Facial dyskinesias that developed with prolonged treatment and that persisted after drug cessation were reported soon after chlorpromazine was introduced (e.g., Schonecker 1957). Because the movements appeared to develop after long-term (> 3 months) FGA treatment, the term *tardive dyskinesia* was coined to describe the persistent OBL dyskinetic movements (Faurbye *et al.* 1964). Given that the persistence of the movements, and not the timing of their onset, is the consistent feature of all tardive syndromes, the descriptive term *tardive*, a French word meaning "delayed" or "late," is a misnomer. Similar to misuse of the term *extrapyramidal* to describe *any* DRB drug-induced movement disorder (Hauser *et al.* 2022; Obeso 2019), use of the term *tardive dyskinesia* to refer to *all* persistent DRB drug-induced motor phenomena likewise causes confusion (Frei *et al.* 2018). For tardive syndromes, use of accurate terminology (e.g., tardive dystonia, tardive akathisia) to describe the observed phenomena is important because the treatment approaches used for the various tardive syndromes differ from the approaches used for the OBL movements of classic TD.

Whereas the general term *dyskinesia* is used to refer to any abnormal involuntary movement, *tardive dyskinesia* (i.e., "classic TD") is the diagnostic term used specifically to denote persistent, involuntary, and stereotyped OBL athetoid or choreiform movements that develop in association with exposure to DRB medications. Most often, antipsychotic drugs (with the possible exception of clozapine) are the responsible agents, but nonpsychiatric medications with DRB properties, such as antiemetics, can also cause TD. Dopamine-depleting drugs have not been shown to cause TD. Movements that resemble those of TD and appear to be caused by medications without DRB properties or by various medical conditions are, by definition, not classified as tardive disorders (D'Abreu and Friedman 2018; Frei *et al.* 2018). In that literature, mostly case reports, medications such as SSRIs or TCAs appear to unmask or exacerbate TD induced by earlier or concurrent use of DRB medications.

Tardive syndrome is the general term comprising persistent, iatrogenic hyperkinetic, hypokinetic, and sensory phenomena that can result from long-term exposure to DRB medications (Frei *et al.* 2018). The various tardive syndromes, classified according to their prevailing phenomena, include classic TD, tardive dystonia, tardive akathisia, tardive tics ("Tourettism"), tardive tremor, tardive myoclonus, and tardive pain and other sensory symptoms (Frei *et al.* 2018). The existence of tardive parkinsonism is under debate, as it may represent an unmasked underlying parkinsonian disorder. In addition to being socially disfiguring, the movements can cause embarrassment and impair function (Savitt and Jankovic 2018).

Although less common than classic TD, *tardive dystonia* is often more disabling. The concurrent presence of classic TD signs and a temporal relationship to DRB agents is useful in distinguishing tardive dystonia from idiopathic dystonia. Tardive dystonia tends to affect the limbs, neck, trunk, or face. Typically, the presentation is a focal dystonia involving neck and face muscles and manifesting as torticollis, retrocollis, or anterocollis, blepharospasm, jaw opening or trismus, grimacing, tongue protrusion, dysphagia, or respiratory stridor accompanied by distress or anxiety (Hauser *et al.* 2022). Sustained dystonia can result in unusual postures (e.g., truncal dystonia with opisthotonic posturing or arm extension and pronation with wrist flexion and internal rotation of the shoulders).

In comparison with classic TD, which is more common in women older than 60 years and tends to occur after lengthy exposure to DRB medication, tardive dystonia is more common in men younger than 40 years and tends to occur sooner after medication exposure. Most older patients will have a focal onset that progresses to segmental dystonia. Younger patients are more likely to present with generalized dystonia. Full remission is more likely in children and less likely in adults (Factor *et al.* 2019).

Tardive akathisia is usually accompanied by other tardive movements. It can persist for up to 7 years after DRB medications are discontinued and is typically resistant to pharmacological treatment (Frei *et al.* 2018). Tardive akathisia resembles acute akathisia in that there is subjective restlessness and tension with objective semi-purposeful or purposeless patterned motor movements (e.g., marching in place, repetitive self-touching, or crossing and uncrossing of legs). Acute akathisia occurs soon after DRB medication exposure, while tardive akathisia usually occurs later and persists or worsens after withdrawal of the offending drug. The presence of other tardive movements facilitates its diagnosis.

Rare tardive variants include DRB drug-induced tics, myoclonus, tremor, and sensory syndromes. Tardive tics, or tardive Tourettism, manifest as motor or vocal tics. Unlike Tourette syndrome, tardive tics have an older age at onset and occur after DRB medication exposure, but the phenomena are otherwise comparable. Tardive myoclonus is rare and is usually evident when the hands are held in certain postures. Tardive tremor tends to be a postural and kinetic tremor rather than a resting tremor. Tardive sensory syndromes can include an urge to move, paresthesias, and pain, or may present as a chronic oral or genital sensation (Frei *et al.* 2018).

Epidemiology

Tardive syndromes are common, affecting an estimated 20%-40% of patients on antipsychotic treatment, despite reduced reporting of TD after the introduction of SGAs and their promise of reduced motor side effects (Martino and Morgante 2017). In a meta-analysis of 41 randomized controlled trials (RCTs) that used FGAs and SGAs for psychotic disorders and were conducted from 2000 to 2015, prevalence of tardive syndromes was 30% among individuals treated with FGAs and 21% among those treated

with SGAs ($P = 0.002$) (Carbon *et al.* 2017). When patients with any FGA exposure were excluded, prevalence in the SGA group declined to 7%. Annual incidence of tardive syndromes in a meta-analysis of 57 RCTs was 6.5% (95% CI = 5.3%-7.8%) for FGAs and 2.6% (95% CI = 2.0%-3.1%) for SGAs (Carbon *et al.* 2018). Whereas SGAs confer a lower overall risk, the prospect of lower prevalence is offset by higher SGA prescribing rates, including off-label uses, a cumulative increased incidence of TD with ongoing antipsychotic use, and the usually irreversible nature of TD (Savitt and Jankovic 2018). Contributing to these rates is the noteworthy threefold increase in antipsychotic prescriptions between 1997 and 2011 in the United States (Friedman 2012). Risk factors for development of TD, aside from DRB medication exposure, include older age, female sex, diabetes mellitus, history of movement or cognitive disorder, intellectual developmental disorder or brain injury, history of DIP or acute DRB drug-induced movement disorder, longer duration of antipsychotic treatment, higher antipsychotic dosage, and family history of TD (Jankelowitz 2013). Commonly, the patient with classic TD is a woman age 60 years or older.

Presentation

Systematic assessments provide a basis for identifying tardive phenomena and monitoring their distribution, severity, and response to treatment (Hauser *et al.* 2022). Behavior and motor abnormalities associated with psychiatric illness, older age, and other drug-induced movements can confound assessment. Although not specifically designed to detect TD, several assessment tools are available that can facilitate baseline screening and longitudinal follow-up of classic TD. Examples are the Abnormal Involuntary Movement Scale (AIMS; Guy 1976; Munetz and Benjamin 1988) and the Dyskinesia Identification System: Condensed User Scale (DISCUS; Kalachnik and Sprague 1993). The Extrapyramidal Symptom Rating Scale (ESRS), a validated tool comparable to the AIMS for assessing classic TD, assesses other drug-induced movement disorders (parkinsonism, akathisia, and dystonia) and discriminates them from clinical psychiatric features (Chouinard and Margolese 2005). The ESRS can be useful since some patients have several DRB medication-induced movement disorders (e.g., elderly individuals are at greater risk for TD and DIP).

In classic TD, movements are hyperkinetic, complex, stereotyped, and rhythmic OBL and chewing movements such as lip smacking, puckering, pursing, sucking, mouth opening and closing, and tongue protrusion (see Hauser *et al.* 2022 for video examples). OBL and similar patterned movements in TD are referred to as *tardive stereotypies*--defined as repetitive, rhythmic, predictable, and often complex patterns of semi-purposeful or purposeless movements that resemble the normal range of movements for that body part, such as gestures or mannerisms. The earliest sign of TD may be a subtle worm-like movement of the tongue inside the mouth. This may evolve to broader side-to-side tongue movements followed by tongue curling, rolling, or twisting or pressing the tongue against the cheek ("bon-bon sign"). "Fly-catcher's tongue" sign refers to brief or prolonged involuntary tongue protrusion. Affected facial muscles cause blinking and blepharospasm. Patients can often suppress the movements voluntarily, such as when asked, while speaking, while eating, or by placing a finger on the lip. When the patient is distracted, the movements tend to increase. More severe TD affects speaking, eating, chewing, and swallowing and can cause oral ulcerations, dental complications, or jaw misalignment.

OBL stereotypies are often accompanied by corresponding repetitive, stereotyped movements of the hands and feet, such as piano-playing movements, hand-rubbing, pelvic thrusting, truncal rocking, foot tapping, or oscillations. Movements of the trunk and neck, however, tend to be irregular and unpredictable choreiform movements. Respiratory dyskinesias affecting the diaphragmatic and intercostal muscles cause irregular respiratory patterns or grunting and may predispose to aspiration. Severe esophageal or respiratory dyskinesias can be life threatening.

Clinical Course

Tardive syndromes usually emerge insidiously after months to years of treatment with a DRB agent or after its discontinuation. There are reports of tardive syndromes developing after brief exposures of several hours or days, but it is rare for tardive movements to begin within the first 3 months of DRB medication treatment. By definition, tardive phenomena require persistent abnormal movements for at least 1 month after stopping the DRB agent. Often, abnormal movements become apparent (i.e., are "unmasked") when the dosage of the offending DRB medication is reduced. Movements that resolve within 1 month of discontinuing the DRB agent can be attributed to acute or subacute DRB drug-induced conditions such as acute dystonia, acute akathisia, DIP, or NMS (Savitt and Jankovic 2018).

After initial symptom onset, the full tardive syndrome evolves over several days to weeks. Severity is highly variable, ranging from mild to severe, but the syndrome can stabilize to a chronic course that sometimes waxes and wanes. Most tardive syndromes persist and are permanent. Remission is reported in fewer than 25% of cases, but symptoms tend to improve over time and after DRB agents are discontinued (Gardos *et al.* 1988). DRB medication withdrawal, especially when abrupt, increases the dyskinesias, referred to as a withdrawal-emergent syndrome that can be avoided by gradual dosage reductions. Increasing the DRB medication dosage, and presumably dopamine blockade, reduces symptoms, a phenomenon referred to as "masked TD" (Savitt and Jankovic 2018).

The presence of multiple tardive disorders or nontardive drug-induced movements in the same patient adds to treatment complexity because treatments for tardive and nontardive syndromes have opposite effects. When there is evidence for a tardive syndrome, a first step is to determine whether acute or subacute DRB drug-induced movement disorders are also present. A tardive syndrome will persist or transiently worsen after dosage reduction or discontinuation of the DRB agent or after the addition of anticholinergic medications, whereas acute dystonia, acute akathisia, and DIP will improve. Managing concurrent tardive dystonia and classic TD is also challenging because their treatments counteract one another. When both are present, the predominant movement abnormality should be addressed.

Prevention

When clinical conditions require long-term treatment with DRB agents, the first arm of treatment is prevention. General caveats are to ensure clear indications for a medication and its duration, preferential use of agents with low risk of inducing TD, use of the lowest clinically effective dosage, minimized use of anticholinergic medications, and scheduled regular evaluations to review indications for the prescribed medication and to screen for signs of TD (and other drug-induced movements). Since patients can lack awareness of their abnormal movements or may not report them, visual observation of patients before and after starting DRB agents and documentation of findings should be a standard practice, including when clinical care is provided virtually. Additional caution and monitoring should be used in individuals with multiple TD risk factors.

Treatment

Initial management requires documentation of the type of phenomena, their severity, and their location or distribution, as well as follow-up diagnostic tests and neurological consultation as indicated; a review of treatment options with the patient and caregivers; and serial follow-up. When evidence supports diagnosis of a tardive syndrome, the first step, if tolerated by the patient, is gradual reduction and withdrawal of the offending agent.

Anticholinergic and antiparkinsonian medications should be discontinued. Anticholinergic agents may exacerbate TD and should not be used to treat TD. When there is significant parkinsonism or tardive dystonia, anticholinergic medications can be tapered gradually over 2 to 4 weeks with monitoring for side effects of anticholinergic cessation or worsening parkinsonism.

When long-term antipsychotic medications are needed, patients may be switched to a lower-potency agent such as quetiapine or clozapine, as these, among the SGAs, have the lowest risk of motor side effects. There are reports of clozapine-induced TD, although most studies support use of clozapine as an effective treatment for TD (Pardis *et al.* 2019). A small meta-analysis of four open-label trials ($n = 48$) (Mentzel *et al.* 2018) and a systematic review (Pardis *et al.* 2019) supported switching to clozapine monotherapy to reduce the risk for tardive movements or to treat a moderate to severe tardive syndrome.

Transient worsening of TD signs during withdrawal of DRB agents can be managed with low-dose benzodiazepines such as lorazepam or clonazepam if there is significant discomfort or anxiety (Bergman *et al.* 2018). If the movements become disabling and need to be suppressed, DRB agents are most effective but limit the prospects for remission.

Vesicular monoamine transporter 2 inhibitors. Development of the highly selective VMAT2 inhibitors valbenazine and deutetrabenazine and conduction of well-designed clinical trials yielded, in 2017, the first drugs specifically approved by the FDA to treat tardive syndrome. When initial management is inadequate, both are considered front-line interventions for TD, including when patients remain on DRB medications (Bhidayasiri *et al.* 2018). In treatment of tardive syndromes, VMAT2 inhibitors block transport of dopamine (and other monoamines) into vesicles at the synaptic cleft, resulting in reduced dopamine concentrations, reduced activation of postsynaptic dopamine receptors in the nigrostriatal pathway, and, consequently, decreased hyperkinetic movements. The main difference between the two drugs is the longer half-life of valbenazine, which is taken once daily at a dosage range of 40-80 mg/day, relative to deutetrabenazine, which is taken twice daily at a dosage range of 12-48 mg/day, must be taken with food, and has better tolerance overall.

Tetrabenazine, an older VMAT2 inhibitor, was approved for dyskinesias in Huntington's disease in 2008. Until the newer VMAT2 inhibitors became available, tetrabenazine

was also used off-label for TD. Its tolerability is influenced by its short half-life requiring three-times-daily dosing, fluctuating plasma levels, and development of somnolence or depression.

Safety concerns, tolerability, and cost are the primary barriers to use of VMAT2 inhibitors. Somnolence is a common side effect. All three VMAT2 inhibitors are metabolized in the liver by cytochrome P450 (CYP) 2D6 and raise concerns for QTc prolongation when prescribed with antipsychotics or CYP2D6 inhibitors, or taken by poor metabolizers. While addition of VMAT2 inhibitors improves TD, reductions in dopamine concentrations can aggravate parkinsonism, parkinsonian tremor, and other acute DRB medication-induced movement disorders to an intolerable degree.

For tardive dystonia or tardive akathisia, there is limited evidence as to whether VMAT2 inhibitors or adjustments in DRB medication dosage or type are beneficial, given that TD treatment trials have not distinguished which tardive subtypes were present. Tardive dystonia may benefit from anticholinergic agents such as benztropine or trihexyphenidyl, but these agents are relatively contraindicated in older patients. Clozapine can be especially beneficial for tardive dystonia when continued use of an antipsychotic is required.

Botulinum neurotoxin injections. Botulinum neurotoxin (BoNT) injections decrease presynaptic cholinergic release. BoNT type A (onabotulinumtoxin A) is approved to treat cranial and cervical dystonia, blepharospasm, and limb spasticity. As there are no RCTs on its use for TD, BoNT has a Level U recommendation (insufficient evidence) in the American Academy of Neurology (AAN) guideline for the treatment of TD (Bhidayasiri *et al.* 2018). Case reports and series and open-label reports suggest benefits of BoNT for TD in individuals with focal dystonia who have not responded to other interventions. While re-injections are required approximately every 3 months in perioral, lingual, or neck areas and have the potential to cause dysarthria and dysphagia, patient satisfaction with the procedure and its results is typically positive (Bashir and Jankovic 2020).

Other treatments. For patients who do not respond to VMAT2 inhibitors or experience intolerable adverse effects, the evidence base of treatment options is inconsistent. As mentioned above, a clozapine trial may be considered prior to or after use of VMAT2 inhibitors (Factor *et al.* 2019). Pathophysiological hypotheses of TD invoking oxidative stress or abnormalities of nondopaminergic neurotransmitters including GABA, glutamate, and acetylcholine have spawned studies on additional treatment approaches. Most of these studies were small and fraught with methodological limitations or nonreplication. However, as most of these medications are available for other indications, *n*-of-1 trials represent an option for individuals who are otherwise treatment nonresponsive or unable to tolerate clozapine or VMAT2 inhibitors.

Amantadine, first reported to reduce TD symptoms in 1971 and often used to treat levodopa-induced dyskinesias, has been prescribed to treat TD in the face of conflicting evidence (Lin and Ondo 2018). Results from several small RCTs of placebo versus amantadine at dosages up to 400 mg/day suggest that amantadine may have short-term benefit for TD at higher dosages than those used for other indications (Level C evidence) (Bhidayasiri *et al.* 2013). Use of amantadine requires monitoring for anticholinergic side effects and the risk for psychosis and livedo reticularis.

Benzodiazepines are frequently used in the treatment of TD, especially in the context of distress or dystonia; evidence for reduced tardive movements is less clear, especially for choreoathetoid movements. In a double-blind RCT crossover trial in which 19 patients with tardive dyskinesia received placebo or clonazepam (in divided doses up to 4.5 mg/day) over a 4-week period (Thaker *et al.* 1987), dyskinesia ratings (Maryland Psychiatric Research Center Scale; Cassady *et al.* 1997) decreased by 37% in participants treated with clonazepam, versus by 2% in those treated with placebo. Because that study has not been replicated, the 2013 AAN guideline stated that clonazepam may be effective for short-term (< 3 months) treatment of TD (Bhidayasiri *et al.* 2013). Small open-label studies of diazepam, alprazolam, and placebo did not demonstrate clear evidence of benefit (Lin and Ondo 2018). Tolerance to benzodiazepines over time and adverse cognitive effects are substantial liabilities.

Several compounds with antioxidant properties have been evaluated for treatment of tardive syndromes. Ginkgo biloba extract (EGb-761) was studied in three RCTs followed by a meta-analysis that showed benefits in TD relative to placebo (Zheng *et al.* 2016). The AAN guideline granted a Level B recommendation to Ginkgo biloba for treatment of TD; however, additional confirmatory studies are needed (Bhidayasiri *et al.* 2018). Small studies on vitamin B_6 (pyridoxal 5'-phosphate) up to 400 mg/day in placebo-controlled RCTs showed reduced dyskinesia scores (Lerner *et al.* 2001, 2007), but there are no reported confirmatory studies.

A meta-analysis showed benefits of vitamin E over placebo in 15 studies (Artukoglu *et al.* 2020), whereas a Cochrane Review of 13 RCTs reported no evidence for benefits of vitamin E over placebo (Soares-Weiser *et al.* 2018). Various other cholinergic agents (e.g., physostigmine, donepezil, deanol, choline, lecithin, meclofenoxate, tacrine) have been evaluated in TD (Lin and Ondo 2018). Trials of cholinesterase inhibitors suggested that these are of limited benefit for TD (Tammenmaa *et al.* 2004). Case reports and open-label trials showed benefits from donepezil for TD, but placebo-controlled RCTs of donepezil (Ogunmefun *et al.* 2009) and of galantamine (Caroff *et al.* 2007) failed to find significant benefits over placebo. Two open-label studies of the branched-chain amino acids leucine, isoleucine, and valine suggested benefits for TD (Richardson *et al.* 1999, 2003), but there are no published follow-up data.

Unlike acute akathisia, tardive akathisia is unlikely to respond to b-blockers, anticholinergics, amantadine, or benzodiazepines.

Neurostimulation. ECT may be beneficial for TD, especially in older patients with concurrent DIP, or as per case reports, when ECT is used to treat depressive illnesses or schizophrenia in patients with concurrent TD (Weiner and Reti 2017). A retrospective case series of 18 patients with TD receiving ECT showed a 10-point improvement in the AIMS score (Yasui-Furukori *et al.* 2014). As other studies failed to show benefits or demonstrated worsening of TD after ECT, AAN guidelines indicate that there is insufficient evidence (Level U) for efficacy of ECT for treatment of TD (Bhidayasiri *et al.* 2013).

Deep brain stimulation (DBS) is used for severe and treatment-refractory TD, usually with tardive dystonia. Further research on efficacy and safety is needed, as most analyses relied on open-label case reports, garnering Level C evidence per AAN guidelines (Bhidayasiri *et al.* 2013). A meta-analysis of 117 patients with refractory tardive syndromes who underwent DBS, primarily targeting the bilateral posteroventral globus

pallidus pars interna, showed evidence for significant improvement on measures of classic TD and dystonia (Macerollo and Deuschl 2018). One RCT evaluated pallidal DBS versus sham treatment for tardive syndromes, including dystonia and dyskinesia (Gruber *et al.* 2018). Group differences in tardive symptom ratings were not statistically significant at 3 months (improvement was 22.8% for DBS vs. 12.0% for sham); at the end of a 6-month open-label extension phase, though, there was an overall improvement of 41.5% and any adverse effects associated with DBS resolved. In the one double-blind RCT of repetitive transcranial magnetic stimulation (rTMS) versus sham over the motor cortex for 10 days ($n = 26$), the active rTMS group had significantly reduced tardive symptoms (Khedr *et al.* 2019).

Summaries of Pharmacological Treatments

Anticholinergic Medications

Trihexyphenidyl

History and discovery. Trihexyphenidyl, a synthetic analog of atropine, was introduced as benzhexol hydrochloride in 1949. It was found to be effective in the treatment of Parkinson's disease in a study of 411 patients (Doshay *et al.* 1954). Thereafter, it was also used to treat antipsychotic-induced parkinsonism (Rashkis and Smarr 1957).

Structure-activity relations. Trihexyphenidyl, a tertiary-amine analog of atropine, is a competitive antagonist of acetylcholine and other muscarinic agonists that compete for a common binding site on muscarinic receptors (Yamamura and Snyder 1974). It exerts little blockade at nicotinic receptors (Timberlake *et al.* 1961). Trihexyphenidyl and all drugs in this class are referred to as anticholinergic, antimuscarinic, or atropine-like drugs. As a tertiary amine, trihexyphenidyl readily crosses the blood-brain barrier (Brown and Taylor 1996).

Pharmacological profile. The pharmacological properties of trihexyphenidyl resemble those of atropine and other anticholinergic drugs, although trihexyphenidyl acts primarily centrally, with few peripheral effects and little sedation. In the eye, anticholinergic drugs block both the sphincter muscle of the iris, causing the pupil to dilate (mydriasis), and the ciliary muscle of the lens, preventing accommodation and causing cycloplegia. In the heart, anticholinergic drugs usually produce a mild tachycardia through vagal blockade at the sinoatrial node pacemaker, although a mild slowing can occur. In the gastrointestinal tract, anticholinergic drugs reduce gut motility and salivary and gastric secretions. Salivary secretion is particularly sensitive and can be completely abolished. In the respiratory system, anticholinergic agents reduce secretions and can produce mild bronchodilatation. Anticholinergics inhibit the activity of sweat glands and mildly decrease contractions in the urinary and biliary tracts (Brown and Taylor 1996).

Pharmacokinetics and disposition. Peak concentration for trihexyphenidyl is reached 1-2 hours after oral administration, and its half-life is 10-12 hours (Cedarbaum and McDowell 1987). As a tertiary amine, trihexyphenidyl crosses the blood-brain barrier to enter the central nervous system (CNS).

Mechanism of action. The presumed mechanism of action of trihexyphenidyl for treatment of acute dystonic reactions or DIP is blockade of intrastriatal cholinergic activity. Compared with nigrostriatal dopaminergic activity, which is decreased by antipsychotic blockade, intrastriatal cholinergic activity is relatively increased. Blockade of cholinergic activity returns the system to its previous equilibrium.

Indications. Trihexyphenidyl, along with the other listed anticholinergics, has FDA approval for treatment of all forms of parkinsonism, including DIP. Trihexyphenidyl can be used to treat acute medication-induced dystonia. Much higher dosages (up to 75 mg/day) have been used for the treatment of primary dystonia. Trihexyphenidyl has limited utility for medication-induced akathisia, except when there is co-occurring DIP.

The benefits of anticholinergic medications are limited by their adverse effects on cognition and memory (Jabbari *et al.* 1989; Taylor *et al.* 1991). Side effects correlate with blood levels, but efficacy does not (Burke and Fahn 1985). The individual therapeutic dosage and duration of is determined empirically and varies widely.

Side effects and toxicology. The *peripheral* side effects of trihexyphenidyl result from its parasympathetic muscarinic blockade and occur in a consistent hierarchy among different organs. They are qualitatively similar to side effects of atropine and other anticholinergic drugs, but are quantitatively less because of the reduced peripheral activity of trihexyphenidyl (Brown 1990).

Anticholinergic drugs initially depress salivary and bronchial secretions and sweat production. Reduced salivation leads to dry mouth and contributes to the high incidence of dental caries found among patients with chronic psychiatric problems (Winer and Bahn 1967). Treatment for this condition is unsatisfactory; relief obtained from chewing sugar-free gum or sucking on hard candy is limited by the need for constant use. Reduced sweating can contribute to heat prostration and heatstroke, particularly in warmer ambient temperatures.

The next physiological effects occur in the eyes and heart. Pupillary dilatation and inhibition of accommodation in the eye lead to photophobia and blurred vision. Attacks of acute glaucoma can occur in susceptible individuals with narrow-angle glaucoma, although this is relatively uncommon. Vagus nerve blockade leads to increased heart rate and is more apparent in patients with high vagal tone (usually younger men).

The next effects are inhibition of urinary bladder function and bowel motility, which can produce urinary retention, constipation, and obstipation. Sufficiently high dosages of anticholinergics will inhibit gastric secretion and motility (Brown and Taylor 1996).

Memory disturbance is the most common *central* side effect of anticholinergic medications because memory is dependent on the cholinergic system (Drachman 1977). Patients with underlying brain pathology are more susceptible to memory disturbance (Fayen *et al.* 1988). Patients with chronic psychiatric conditions often have a decreased ability to express themselves, making evaluation of memory more difficult; therefore, subtle memory changes can be missed or attributed to the underlying illness.

Memory disturbances are aggravated in patients with Parkinson's disease treated with anticholinergics (Yahr and Duvoisin 1968), even in some patients receiving only small dosages (Stephens 1967). For example, patients receiving an antipsychotic and benztropine had significantly increased overall scores on the Wechsler Memory Scale when benztropine was withdrawn (Baker *et al.* 1983).

Anticholinergic toxicity produces restlessness, irritability, disorientation, hallucinations, and delirium. Elderly patients are at increased risk for both memory loss and toxic delirium, even at very low dosages, because of the natural loss of cholinergic neurons with aging (Perry *et al.*

1977). Toxic dosages can produce a clinical situation identical to atropine poisoning, manifesting as fixed dilated pupils, flushed face, sinus tachycardia, urinary retention, dry mouth, and fever. This condition can proceed to coma, cardiorespiratory collapse, and death.

Drug-drug interactions. Anticholinergic effects, including side effects, may increase when trihexyphenidyl or any anticholinergic is combined with amantadine. Anticholinergic side effects are also more likely to occur when these agents are combined with other drugs with anticholinergic properties.

As to whether anticholinergic medications affect antipsychotic blood levels, the best studies indicate that anticholinergic drugs either do not affect antipsychotic blood levels, or, at most, lower these levels only transiently (McEvoy 1983).

Anticholinergic abuse. Anticholinergic drugs may be abused for their euphoriant and hallucinogenic effects, or combined with street drugs for enhanced effect (Crawshaw and Mullen 1984). The abuse potential of anticholinergic drugs in psychiatric and nonpsychiatric patients is attributed to their indirect effect as a dopamine agonist in the limbic system (Naja and Halaby 2017). Patients with a history of substance abuse have a greater potential to abuse anticholinergics. However, in some individuals with schizophrenia who used higher-than-prescribed dosages, reports of "abuse" were associated with reduced antipsychotic-induced anhedonia, improved function, and minimal, if any, adverse anticholinergic effects (Wells *et al.* 1989). Cases of abuse are reported with all anticholinergics, but trihexyphenidyl is the drug for which abuse is most frequently reported, followed by benztropine (Chiappini *et al.* 2022). It is unclear whether the higher reported rates of abuse of these agents is related to their unique properties versus their greater general availability relative to other anticholinergic medications.

Benztropine

History and discovery. Benztropine was synthesized by uniting the tropine portion of atropine with the benzhydryl portion of diphenhydramine hydrochloride. Benztropine was found to be effective in the treatment of

302 patients with Parkinson's disease (Doshay 1956). The best results in the control of rigidity, contracture, and tremor were obtained at benztropine dosages of 1-4 mg once daily for older patients and 2-8 mg once daily for younger ones. Dosages of 15-30 mg once daily caused excessive flaccidity in some patients, who became unable to lift their arms or raise their heads off the bed. Subsequently, benztropine was found to be effective for treatment of DIP (Karn and Kasper 1959).

Structure-activity relations. Benztropine is a tertiary amine with activity similar to that of trihexyphenidyl. As a tertiary amine, benztropine enters the CNS.

Pharmacological profile. Benztropine has the pharmacological properties of an anticholinergic and an antihistaminic; however, it produces less sedation (in experimental animals) than diphenhydramine.

Pharmacokinetics and disposition. Little is known about the pharmacokinetics of benztropine. A correlation between serum anticholinergic levels and the presence of DIP is documented (Tune and Coyle 1980). There is little correlation between the total daily dosage of benztropine and the serum anticholinergic level, with the serum activity for a given dosage varying 100-fold between subjects. When treated with higher dosages of anticholinergics, patients with DIP show increased serum anticholinergic activity and decreased abnormal movements. Relatively small increases in the oral dosage of an anticholinergic drug can result in significant nonlinear increases in serum anticholinergic activity levels. Benztropine has a long-acting effect and can be given once or twice a day.

Mechanism of action, side effects, and drug-drug interactions.

The mechanism of action and the drug interactions for benztropine are similar to those of trihexyphenidyl. The side effects of these two drugs are also similar, but the degree of sedation produced by benztropine may be less (Doshay 1956).

Indications. Benztropine, like the other listed anticholinergics, has FDA approval for use in the treatment of all forms of parkinsonism, including

DIP. Intramuscular benztropine is a first-line treatment for acute dystonic reactions.

Biperiden

Biperiden, not currently available in the United States, is an analog of trihexyphenidyl that has greater peripheral anticholinergic activity than trihexyphenidyl and greater activity against nicotinic receptors (Timberlake *et al.* 1961). Biperiden is well absorbed from the gastrointestinal tract. Its metabolism, while not completely understood, involves liver hydroxylation. Its activity, pharmacological profile, and side effects resemble those of other anticholinergics. It is indicated for treatment of DIP.

Procyclidine

Procyclidine is an analog of trihexyphenidyl (Schwab and Chafetz 1955). Its activity, pharmacology, and side effects resemble those of other anticholinergics. It is indicated for treatment of DIP. The limited pharmacokinetic data show that it is rapidly absorbed, with a 12-hour half-life after oral or intravenous administration, extensive metabolism in the liver, and a relatively low urine clearance rate. Accordingly, dosage adjustments are indicated in older persons or in individuals with hepatic dysfunction (Whiteman *et al.* 1985).

Antihistaminic Medications

Diphenhydramine

History and discovery. Antihistaminic agents have been used for the treatment of Parkinson's disease. Diphenhydramine, one of the first antihistamines developed and used clinically (Bovet 1950), was the primary antihistamine studied in treatment of DIP. Although some antihistamines may be effective, other antihistamines have not been studied systematically for treatment of DIP.

Structure-activity relations. All drugs referred to as antihistamines are reversible competitive inhibitors of histamine at the histamine 1 (H_1)

receptor. Some antihistamines also inhibit the action of acetylcholine at the muscarinic receptor. It is believed that central muscarinic blockade, rather than histaminic blockade, is responsible for the therapeutic effect of antihistamines in DIP or acute dystonic reactions. Ethanolamine antihistamines (i.e., diphenhydramine, dimenhydrinate, and carbinoxamine maleate) have the greatest anticholinergic activity, and ethylenediamine antihistamines have the least anticholinergic activity. Antihistamines such as terfenadine and astemizole have no anticholinergic activity, whereas many of the remaining antihistamines have very mild anticholinergic activity (Babe and Serafin 1996).

Pharmacological profile. Antihistamines inhibit the constrictor action of histamine on respiratory smooth muscle. They restrict the vasoconstrictor and vasodilatory effects of histamine on vascular smooth muscle and block histamine-induced capillary permeability. Antihistamines with CNS activity are depressants, producing diminished alertness, slowed reaction times, and somnolence. They can also block motion sickness. Antihistaminic drugs with anticholinergic activity also possess mild antimuscarinic pharmacological properties similar to those of other atropine-like drugs (Babe and Serafin 1996).

Pharmacokinetics and disposition. Diphenhydramine is well absorbed from the gastrointestinal tract. Peak concentrations occur 2-3 hours after oral administration. Its therapeutic effects usually last 4-6 hours, and it has a half-life of 3-9 hours. Diphenhydramine is widely distributed throughout the body, and as a tertiary amine, it enters the CNS. Age does not affect its pharmacokinetics. It undergoes demethylations in the liver and is then oxidized to carboxylic acid (Paton and Webster 1985).

Mechanism of action. Diphenhydramine possesses some anticholinergic activity, which is believed to be the basis for its effect in diminishing DIP and acute dystonic reactions.

Indications. Diphenhydramine has FDA approval for treatment of parkinsonism, including DIP, in the elderly and for mild cases of parkinsonism in other age groups. It is used as an oral or parenteral agent to treat acute dystonic reactions. There is no conclusive evidence that it is helpful for akathisia or nonparkinsonian tremor. Diphenhydramine also has indications for multiple other conditions that are not related to drug-induced movement disorders.

Side effects and toxicology. The primary side effect of diphenhydramine is sedation. Although other antihistamines may cause gastrointestinal distress, diphenhydramine has a low incidence of such an effect. Drying of the mouth and respiratory passages can occur. In general, the toxic effects are similar to those of trihexyphenidyl and of other anticholinergics.

Drug-drug interactions. Diphenhydramine has no reported interactions with other drugs, but it has an additive depressant effect when used in combination with alcohol or with other CNS depressants.

Dopaminergic Medications

Amantadine

History and discovery. Anticholinergic side effects and inadequate treatment response eventually led to the investigation of other agents to treat antipsychotic-induced movement disorders. Initially, both methylphenidate and intravenous caffeine

were investigated as treatments for DIP, but neither agent achieved general use, despite apparent efficacy (Brooks 1956; Freyhan 1959).

Amantadine is an antiviral agent that is effective against A2 (Asian) influenza (Wingfield *et al.* 1969). It was unexpectedly found to produce symptomatic improvement in patients with Parkinson's disease (Parkes *et al.* 1970; Schwab *et al.* 1969). Subsequently, it was reported as effective for DIP (Kelly and Abuzzahab 1971).

Structure-activity relations. Amantadine is a water-soluble tricyclic amine. It binds to the Matrix-2 (M2) protein, a membrane protein that functions as an ion channel on the influenza A virus (Hay 1992). Its activity in reducing DIP is not known. Earlier animal studies implicated direct and indirect effects on dopamine neurons. More recent studies demonstrated weak, noncompetitive *N*-methyl-D-aspartate antagonist effects with antiglutamatergic properties. Clinically, anticholinergic-like side effects are evident (e.g., dry mouth, urinary retention, constipation), despite the fact that the drug does not possess direct anticholinergic activity in animal studies, although it has been shown to have activity at glutamate receptors (Stoof *et al.* 1992).

Indications. Amantadine has FDA approval for the treatment and prophylaxis of influenza A respiratory illness and for the treatment of Parkinson's disease and secondary causes of parkinsonism, including DIP, postencephalitic parkinsonism, and parkinsonism associated with carbon monoxide intoxication or cerebral arteriosclerosis. Amantadine is commonly used in the management of levodopa-induced dyskinesias (Vijayakumar and Jankovic 2016). Amantadine has a Level C recommendation for the treatment of TD (Bhidayasiri *et al.* 2018) based on initial small case series and mixed results from two small RCTs (Angus *et al.* 1997; Pappa *et al.* 2010).

Limited data show that amantadine may benefit a small number of patients with akathisia, but there is insufficient evidence to recommend its use for that purpose.

Pharmacokinetics and disposition. In young healthy individuals, amantadine is slowly and well absorbed from the gastrointestinal tract, with unchanged oral bioavailability over a dosage range of 50-300 mg/day. It reaches steady state in 4-7 days. Plasma concentrations (0.12-1.12 mg/mL) may have some correlation with improvement in DIP (Greenblatt *et al.* 1977; Pacifici *et al.* 1976). Amantadine has relatively constant blood levels and a long duration of action (Aoki *et al.* 1979) and is excreted unchanged by the kidneys. Its elimination half-life is 16-17 hours and is more prolonged in elderly individuals and patients with impaired renal function (Hayden *et al.* 1985).

Mechanism of action. Amantadine inhibits viral replication by binding to the M2 protein on the viral membrane and inhibiting replication (Hay 1992). Its mechanism of action as an antiparkinsonian agent is less clear.

Amantadine has no anticholinergic activity in tests on animals, being only 1/209,000 as potent as atropine (Grelak *et al.* 1970). It appears to cause the release of dopamine and other catecholamines from intraneuronal storage sites via an amphetamine-like mechanism. It has also been shown to have activity at glutamate receptors, which may contribute to its antiparkinsonian effect (Stoof *et al.* 1992). Amantadine has preferential selectivity for central catecholamine neurons (Grelak *et al.* 1970; Stromberg *et al.* 1970).

Side effects and toxicology. At dosages of 100-300 mg/day, amantadine does not produce adverse effects as readily as do anticholinergic medications. Side effects of amantadine result from CNS stimulation. The most common reported side effects are nausea, dizziness (lightheadedness), and insomnia. Other side effects include irritability, tremor, dysarthria, ataxia, vertigo, agitation, reduced concentration, hallucinations, and delirium (Postma and Van Tilburg 1975). Hallucinations are often visual. Side effects are more likely to occur in elderly patients and in patients with reduced renal function (Borison 1979; Ing *et al.* 1979). Toxic effects are directly related to elevated amantadine serum levels (> 1.5 mg/mL). Resolution of toxic symptoms is dependent on renal clearance and may require dialysis in extreme cases, although less than 5% of amantadine is removed through dialysis.

Patients with congestive heart failure or peripheral edema should be monitored because of amantadine's ability to increase the availability of catecholamines. Long-term use of amantadine may produce livedo reticularis in the lower extremities from the local release of catecholamines and resulting vasoconstriction (Cedarbaum and Schleifer 1990). Amantadine should be used with caution in patients with seizures because of possible increased seizure activity. Amantadine is embryotoxic and teratogenic in animals, but there are no well-controlled studies in women regarding teratogenicity.

Drug-drug interactions. There are no reported interactions between amantadine and other drugs. There may be increased anticholinergic side effects when amantadine is used in combination with an anticholinergic agent.

Other precautions. Amantadine should not be discontinued abruptly, because this can result in an acute parkinsonian crisis or precipitate delirium, agitation, delusions, hallucinations, paranoia, stupor, anxiety, depression, or slurred speech. Cases of possible NMS have also been reported after dosage reductions or withdrawal of amantadine, warranting careful observation, especially in patients prescribed DRB agents, when the amantadine dosage is abruptly reduced or the drug is discontinued.

Amantadine dosages should be reduced in patients with renal impairment and in individuals age 65 years or older. Reduced dosages may also be required in the context of congestive heart failure, peripheral edema, or orthostatic hypotension.

Beta-Adrenergic Receptor Antagonists

History and Discovery

Propranolol was reported to be effective for the treatment of restless legs syndrome (Ekbom syndrome [Ekbom 1965]), which resembles the physical movements of akathisia (Strang 1967). Later it was reported to be effective in the treatment of medication-induced akathisia (Kulik and Wilbur 1983; Lipinski *et al.* 1983). Subsequently, other b-blockers have been investigated for the treatment of akathisia.

Structure-Activity Relations

Competitive b-adrenergic receptor antagonism is a property common to all b-blockers. b-Blockers are distinguished by the additional properties of their relative affinity for b_1 and b_2 receptors (selectivity), lipid solubility, intrinsic b-adrenergic receptor *agonist* activity, blockade of receptors, capacity to induce vasodilation, and general pharmacokinetic properties (Hoffman and Lefkowitz 1996). b-Blockers with high lipid solubility readily cross the blood-brain barrier.

Pharmacological Profile

The major pharmacological effects of b-blockers involve the cardiovascular system. b-Blockers slow the heart rate and decrease cardiac contractility; however, these effects are modest in a normal heart. In the lung, they can cause bronchospasm, although, again, there is little effect in normal lungs. They block glycogenolysis, preventing production of glucose during hypoglycemia (Hoffman and Lefkowitz 1996). b-Blockers affect lipid metabolism by preventing release of free fatty acids while elevating triglycerides (Miller 1987). In the CNS, they produce fatigue, sleep disturbance (insomnia and nightmares), and CNS depression (see Drayer 1987; Gengo *et al.* 1987).

All b-blockers, except atenolol and nadolol, are well absorbed from the gastrointestinal tract (McDevitt 1987). All b-blockers undergo metabolism in the liver. Propranolol and metoprolol undergo significant first-pass effects, with bioavailability as low as 25%. Large interindividual variation (as much as 20-fold) leads to wide variation in clinically therapeutic dosages (Hoffman and Lefkowitz 1996). Metabolites appear to have limited b-receptor antagonistic activity. The degree to which a particular b-blocker enters the CNS is related directly to its lipid solubility.

Mechanism of Action

The exact mechanism of action of b-blockers in the treatment of drug-induced abnormal movements is unclear. The existence of a noradrenergic pathway from the locus coeruleus to the limbic system has been proposed as a modulator involved in symptoms of TD, akathisia, and tremor (Wilbur *et al.* 1988). It appears that lipid solubility and the corresponding ability to enter the CNS are the most important factors determining the efficacy of a b-blocker in treating akathisia and perhaps other types of drug-induced abnormal movements (Adler *et al.* 1991).

Indications

b-Blockers have FDA approval primarily for cardiovascular indications, and propranolol is also indicated for familial essential tremor, but there are no

FDA-approved indications for the treatment of any type of medication-induced movement disorders.

b-Blockers are considered to be the first-line treatment for akathisia. In addition to their indication for essential tremor, b-blockers have been reported to be beneficial for tremor in Parkinson's disease (Foster *et al.* 1984) and for lithium-induced tremor (Gelenberg and Jefferson 1995), but not for antipsychotic-induced tremor (Metzer *et al.* 1993).

Side Effects and Toxicology

The side effects of b-blockers result from b-receptor blockade. b_2-Blockade of bronchial smooth muscle produces bronchospasm. Individuals with normal lung function are unlikely to be affected, but smokers and others with lung disease can develop serious breathing difficulties. b-Blockers can contribute to heart failure in susceptible individuals, such as those with compensated heart failure, acute myocardial infarction, or cardiomegaly. Abrupt cessation of b-blockers can also exacerbate coronary heart disease in susceptible patients, producing angina or, potentially, myocardial infarction (for details, see Hoffman and Lefkowitz 1996).

In individuals with normal heart function, bradycardia produced by b-blockers is insignificant; however, in patients with conduction defects or when combined with

other drugs that impair cardiac conduction, b-blockers can contribute to serious conduction problems.

b-Blockers can block the tachycardia associated with hypoglycemia, eliminating this warning sign in patients with diabetes. b_2 blockade also can inhibit glycogenolysis and glucose mobilization, interfering with recovery from hypoglycemia (Hoffman and Lefkowitz 1996).

b-Blockers can impair exercise performance and produce fatigue, insomnia, and major depressive disorder. However, the development of major depressive disorder probably only occurs in individuals predisposed to developing an affective disorder.

Drug-Drug Interactions

b-Blockers can have significant interactions with other drugs. Chlorpromazine in combination with propranolol may increase the blood levels of both drugs. Additive effects on cardiac conduction and blood pressure can occur when b-blockers are combined with drugs having similar effects (e.g., calcium channel blockers). Phenytoin, phenobarbital, and rifampin increase the clearance of propranolol. Cimetidine increases propranolol blood levels by decreasing hepatic metabolism. Theophylline clearance is reduced by propranolol. Aluminum salts (antacids), cholestyramine, and colestipol may reduce the absorption of b-blockers (Hoffman and Lefkowitz 1996).

Benzodiazepines

History and Discovery

Diazepam was first shown to be effective in the treatment of restless legs syndrome (Ekbom syndrome), which resembles the physical movements of akathisia (Ekbom 1965). Subsequently, diazepam, lorazepam, and clonazepam were reported to be beneficial for medication-induced akathisia (Adler *et al.* 1985; Donlon 1973; Kutcher *et al.* 1987). Clonazepam was reported to be beneficial for drug-induced dystonia (O'Flanagan 1975) and TD (Thaker *et al.* 1987).

Mechanism of Action

All benzodiazepines promote binding of GABA to $GABA_A$ receptors, magnifying the effects of GABA. The mechanism by which these agents improve antipsychotic-induced movement disorders is unknown, but it may be related to their augmentation of the inhibitory GABAergic effect (Hobbs *et al.* 1996). The properties of benzodiazepines are discussed in detail in Chapter 22.

Indications

Benzodiazepines have FDA approval for use in treatment of anxiety disorders, agoraphobia, insomnia, and seizure disorders; management of alcohol withdrawal; anesthetic premedication; and skeletal muscle relaxation. Although benzodiazepines are not approved to treat any specific medication-induced movement disorders, they are sometimes used to reduce anxiety, distress, or agitation associated with an acute drug-induced movement disorder.

Lorazepam and clonazepam are the two primary benzodiazepines studied in the treatment of drug-induced movement disorders. Clonazepam has a long duration of action and can be given once a day. Lorazepam (intermediate-acting) has the advantage of possessing no active metabolites, which limits its potential side effects and toxicity. Short-term benzodiazepine use can have some utility for drug-induced movement disorders when there is significant distress or agitation. Otherwise, the risks of diversion, falls, and cognitive effects with any duration of use are compounded by the development of tolerance and risks of dependence and withdrawal with longer-term benzodiazepine use (Pringsheim *et al.* 2018).

In the remote past, clonazepam was reported as effective in the treatment of TD (Bobruff *et al.* 1981; Thaker *et al.* 1990). Dosages of 1-10 mg/day were used in the first study (Bobruff *et al.* 1981), although the optimal dosage was found to be 4 mg/day, with many patients unable to tolerate higher dosages. The second study used dosages of 2-4.5 mg/day, and tolerance developed after 5-8 months (Thaker *et al.* 1990). Other studies were limited by short durations and small sample sizes, with subjects also receiving antiparkinsonian agents.

A relatively recent systematic review (Bergman *et al.* 2018) on the effectiveness of benzodiazepines as adjunctive treatment for TD identified four small RCTs, comprising a total of 75 individuals with antipsychotic-induced TD. The absence of differences between treatment groups in the improvement in TD features and the low quality of the evidence led the authors to conclude that benzodiazepines are not indicated for routine clinical use and that any use should be considered experimental, and warrants caution, given the risk for adverse effects (Bergman *et al.* 2018).

A systematic review examining the treatment of antipsychotic-induced akathisia reported on two small RCTs of 7-14 days' duration comparing clonazepam with placebo across a total of 27 participants (Pringsheim *et al.* 2018). In both studies, clonazepam was significantly beneficial and well-tolerated, supporting its use as an option for short-term treatment, starting at a dosage of 0.5 mg/day, with slow titration to the lowest effective dosage.

Botulinum Toxin

History and Discovery

Botulinum toxin, produced by *Clostridium botulinum,* causes botulism when ingested. The first clinical use of this toxin was in the treatment of childhood strabismus (Scott 1980), and its first use to treat a focal dystonia was with blepharospasm (Elston 1988). Since these first uses, botulinum toxin has been used to treat many other conditions associated with excessive muscle activity, including medication-induced dystonias (Hughes 1994).

Structure-Activity Relations

There are seven immunologically distinct botulinum toxins (Simpson 1981). Type A is the primary type used clinically (Hambleton 1992). Type F and possibly type B also have clinical utility, but they have much shorter durations of action ([?] 3 weeks, compared with [?] 3 months for type A) (Borodic *et al.* 1996). The toxin is quantified by bioassay and is expressed in "mouse units" (i.e., the dose that is lethal to 50% of animals following intraperitoneal injection [Quinn and Hallet 1989]).

Pharmacological Profile

Botulinum toxin binds to cholinergic motor nerve terminals, preventing release of acetylcholine and producing a functionally denervated muscle. Prevention of acetylcholine release occurs within a few hours, but the clinical effect does not occur for 1-

3 days. The innervation is gradually restored, although the number or size of active muscle fibers is reduced (Odergren *et al.* 1994).

Pharmacokinetics and Disposition

After binding to the presynaptic nerve terminal, the toxin is taken into the nerve cell and metabolized. When antibodies are present, the toxin is metabolized by immunological processes.

Mechanism of Action

Botulinum toxin acts presynaptically to prevent the release of acetylcholine at the neuromuscular junction. This blockade produces a functional chemical denervation and paralysis of the muscle. When botulinum toxin is used clinically, the aim is to reduce the excessive muscle activity without producing significant weakness (Hughes 1994).

Indications

The FDA has approved the use of botulinum toxin for strabismus, blepharospasm, and other facial nerve disorders (see Jankovic and Brin 1991). Botulinum toxin is used to treat focal neuroleptic-induced dystonias that may occur as part of TD, including laryngeal dystonia (Blitzer and Brin 1991) and refractory torticollis (Kaufman 1994). For laryngeal dystonia, the toxin is injected percutaneously through the cricothyroid membrane into the thyroarytenoid muscle bilaterally. The response rate is 80%-90%, and the effect lasts 3-4 months and sometimes longer. Botulinum treatment is effective for tardive cervical dystonia; the observed improvement was similar to the improvement seen in the treatment of idiopathic cervical dystonia, although patients with tardive cervical dystonia required higher doses (Brashear *et al.* 1998).

Side Effects and Toxicology

The major potential side effect of botulinum toxin is focal weakness in the injected muscle group, an effect that is usually dose dependent. This effect is generally temporary, given the mechanism of action. Transient weakness also can occur through diffusion of toxin into surrounding noninjected muscles (Hughes 1994).

Antibodies to the toxin can develop and can prevent a therapeutic response, particularly for the next few treatments. The two main factors contributing to the development of antibodies are young age at first treatment with the toxin and total cumulative dose (Jankovic and Schwartz 1995). Some individuals with antibodies will respond to other botulinum serotypes, such as type F (Greene and Fahn 1993). Local skin reactions also can occur. Some degree of muscle atrophy is apparent in injected muscles (Hughes 1994). Reinnervation usually takes place over the course of 3-4 months (Odergren *et al.* 1994).

Botulinum toxin has no known contraindications. Because the effect on the fetus is unknown, use of the toxin is not recommended during pregnancy. In conditions in which there are neuromuscular junction disorders, such as myasthenia gravis, patients could theoretically experience increased weakness. The long-term effects are unknown (Hughes 1994).

Drug-Drug Interactions

Botulinum toxin has no known interactions with other drugs.

Vitamin E (Alpha-Tocopherol) for Tardive Dyskinesia

History and Discovery

Vitamin E was proposed as a treatment for TD after it was noted that administration of a neurotoxin to rats induced an irreversible movement disorder and axonal damage similar to that caused by vitamin E deficiency. It was proposed that long-term antipsychotic use might produce free radicals, which would contribute to neurological damage and TD, and that the antioxidant effect of vitamin E could attenuate the damage (Cadet *et al.* 1986).

Indications

The only known indication for vitamin E is treatment of vitamin E deficiency, which almost always results from malabsorption syndromes or abnormal transport, such as with abetalipoproteinemia (Bieri and Farrell 1976).

Early studies of vitamin E treatment of TD reported findings ranging from general benefit (Adler *et al.* 1993b; Dabiri *et al.* 1994; Lohr *et al.* 1988) to benefit only in subjects with TD of fewer than 5 years' duration (Egan *et al.* 1992; Lohr and Caligiuri 1996) to no benefit (Schmidt *et al.* 1991; Shriqui *et al.* 1992). Subsequently, a major double-blind study comparing vitamin E with placebo found that vitamin E was no more beneficial than placebo (Adler *et al.* 1999). There were no significant effects of vitamin E on total scores or subscale scores on the AIMS (Guy 1976), on electromechanical measures of dyskinesia, or on scores for four other scales measuring dyskinesia. The authors concluded that there was no evidence for efficacy of vitamin E in the treatment of TD (Adler *et al.* 1999).

The use of vitamin E supplementation is not without risk. A meta-analysis of high-dosage vitamin E supplementation trials showed a statistically significant association between vitamin E dosage and all-cause mortality, with increased risk for dosages greater than 150 IU/day (Miller *et al.* 2005). Given the lack of data showing its consistent effectiveness for TD, vitamin E is not recommended for this purpose.

Side Effects and Toxicology

Side effects are minimal when vitamin E is given orally. High levels of vitamin E can exacerbate bleeding abnormalities that are associated with vitamin K deficiency. Dosages of up to 3,200 mg/day in studies for other conditions have been used without significant adverse effects (Kappus and Diplock 1992). The only known drug interactions are with vitamin K (when it is being given for a deficiency and bleeding abnormalities) and possibly with oral anticoagulants. High dosages of vitamin E can exacerbate the coagulation abnormalities in both cases and therefore are contraindicated (Kappus and Diplock 1992).

Vesicular Monoamine Transporter 2 Inhibitor Drugs

History and Discovery

Tetrabenazine, a reversible and specific inhibitor of VMAT2, was initially developed in the 1950s. The use of tetrabenazine as a treatment for TD was first reported in 1972 (Kazamatsuri *et al.* 1972). Subsequently, tetrabenazine was approved for use in treating hyperkinetic movement disorders in several countries, including Canada, France, Germany, Spain, and the UK. In 2008, tetrabenazine received U.S. FDA approval as an orphan drug to treat chorea in Huntington's disease. Efforts to retain the efficacy of tetrabenazine and address its safety profile, including significant akathisia and parkinsonism, led to development of valbenazine and deutetrabenazine, and in 2017, these agents became the first drugs to be approved by the FDA specifically for the treatment of tardive syndromes.

Prior to their approval, valbenazine and deutetrabenazine were evaluated in well-designed randomized, double-blind, placebo-controlled efficacy trials. The primary outcome measure in both trials was the change in the AIMS score, based on ratings of randomized video segments by a central panel of movement disorder specialists who were blinded to treatment assignment. Neither of the trials specified which tardive subtypes were present.

For valbenazine, the Phase II (KINECT2, $n = 100$) (O'Brien *et al.* 2015) and Phase III (KINECT3, $n = 225$) (Hauser *et al.* 2017) studies were randomized, placebo-controlled, double-blind 6-week trials. Subjects received placebo or valbenazine (escalated up to 75 mg/day in KINECT2 and administered in dosages of 40 mg/day or 80 mg/day in KINECT3). DRB agents were continued at stable dosages during the trial. Both studies found that valbenazine treatment, relative to placebo, was associated with a significantly greater dose-dependent reduction in AIMS scores. A 42-week extension study of the KINECT3 trial maintained the valbenazine group on their randomly assigned dosages and re-randomized the placebo-treated subjects to either 40 mg or 80 mg valbenazine daily (Factor *et al.* 2017).

Reductions in AIMS scores continued in all groups over the 42 weeks, and long-term safety was demonstrated. After a 4-week washout of valbenazine, AIMS scores returned to baseline levels.

The two deutetrabenazine studies for treatment of tardive syndrome, each 12 weeks in duration, demonstrated significantly greater reductions in AIMS scores at deutetrabenazine dosages of 24 mg/day or higher compared with placebo. The Phase II ARM-TD study (n = 117) (Fernandez *et al.* 2017) compared placebo against deutetrabenazine (up to 24 mg twice daily). In the Phase III AIM-TD study (n = 298) (Anderson *et al.* 2017), subjects were randomly assigned to placebo or deutetrabenazine 12 mg/day, 24 mg/day, or 36 mg/day.

Structure-Activity Relations

Tetrabenazine, deutetrabenazine, and valbenazine are reversible VMAT2 inhibitors, which is the basis for their mechanism of action in hyperkinetic movement disorders. Following reuptake of monoamine neurotransmitters from the synaptic cleft into the neuron, VMAT2, a key protein found only in central presynaptic neurons, transports cytosolic dopamine, norepinephrine, and serotonin into presynaptic vesicles for synaptic release. VMAT2 inhibition prevents this packaging of monoamines, which are then degraded by MAO. As a result, presynaptic dopamine levels are reduced, as is the overstimulation that leads to involuntary movements. Nonselective VMAT inhibition, such as with reserpine, also inhibits VMAT1, which is localized in both the central and peripheral nervous systems and is associated with peripheral adverse effects including hypotension, bronchospasm, nausea, and vomiting.

Pharmacokinetics and Disposition

Tetrabenazine is metabolized via hepatic isoenzyme CYP2D6 into a-dihydrotetrabenazine and b-dihydrotetrabenazine. The half-life of tetrabenazine is 5-7 hours, necessitating dosing three times daily. Its side-effect profile and need for frequent dosing restricted use of tetrabenazine and led to the development of the novel VMAT2 inhibitors valbenazine and deutetrabenazine. Valbenazine was developed as a purified prodrug of dihydrotetrabenazine linked to a valine molecule, which prolongs its half-life for 15-22 hours and allows for once-daily dosing. The limited range of active metabolites of valbenazine reduces off-target binding, as is seen with tetrabenazine. In deutetrabenazine, hydrogen in tetrabenazine is replaced with deuterium, a nonradioactive isotope that renders the drug more resistant to hepatic isoenzymes. As a result, clearance is slower and peak concentrations of tetrabenazine are lower, providing a basis for the increased tolerability of deutetrabenazine and its reduced side effects. The half-life of deutetrabenazine is 9-10 hours, and dosing is twice daily.

Indications and Dosing

Valbenazine and deutetrabenazine are the only drugs approved by the FDA specifically for the treatment of TD. Tetrabenazine was approved in 2008 for the treatment of chorea in Huntington's disease and has been used off-label for TD. Deutetrabenazine was approved in 2017 for the treatment of chorea in Huntington's disease.

When used to treat tardive syndromes, valbenazine and deutetrabenazine differ in their dosing frequency, contraindications, warnings/precautions, drug interactions, and cost. Although no trials have directly compared valbenazine and deutetrabenazine, systematic reviews and meta-analyses have demonstrated that the two drugs have comparable efficacy in reducing AIMS scores and similar tolerability (Artukoglu *et al.* 2020; Patel *et al.* 2019; Solmi *et al.* 2018). The recommended dosage range for valbenazine is 40-80 mg/day given once daily, and that for deutetrabenazine is 6-48 mg/day divided into two doses. Because of its rapid metabolism, tetrabenazine needs to be started at a low dosage (12.5-25 mg/day) and titrated upward with monitoring for adverse effects. A typical therapeutic dosage of tetrabenazine is 50-75 mg/day divided into three doses.

Side Effects and Toxicology

Common adverse effects of VMAT2 inhibitors include somnolence, depression, parkinsonism, and akathisia. Valbenazine has also been associated with dry mouth, dizziness, and headache, and deutetrabenazine with insomnia and nasopharyngitis. All three VMAT2 inhibitors have warnings and precautions for parkinsonism, sedation/somnolence, and QTc prolongation. Individuals taking deutetrabenazine or tetrabenazine should be monitored for depression and suicidality; NMS; akathisia, restlessness, and agitation; hyperprolactinemia, and binding to melanin-containing tissues. In addition, tetrabenazine can cause hypotension and orthostatic hypotension.

Drug-Drug Interactions

The presence of hepatic impairment requires care in the choice of VMAT2 inhibitor for TD management. The three VMAT2 inhibitors have significant drug-drug interactions with strong CYP2D6 inhibitors and monoamine oxidase inhibitors. Additionally, valbenazine interacts with strong CYP3A4 inhibitors and CYP3A4 inducers and digoxin. Deutetrabenazine and tetrabenazine also have significant interactions with reserpine, alcohol and sedating drugs, antipsychotic agents, and concomitant VMAT2 inhibitors. Tetrabenazine has significant interactions with drugs causing QTc prolongation.

Conclusion

Drug-induced movement disorders are a significant complication of psychiatric and nonpsychiatric medications that can be disfiguring, distressing, and even life-threatening. Accurate diagnosis of these iatrogenic conditions requires characterization of the movement phenomena and careful history-taking regarding medication use, duration of exposure to potentially causative agents, and timing of the onset of the movement abnormality relative to the medication exposures. Even though antipsychotic medications are typically cited as culprits of acute dystonia, acute akathisia, drug-induced parkinsonism, and tardive syndromes, commonly used mood stabilizers and antidepressants and nonpsychiatric medications also cause abnormal movements and warrant attention. Prudent prescribing practices, patient and caregiver education, visual observation of the patient, and systematic serial assessments are the cornerstones of prevention and early identification of drug-induced movement disorders. When required, treatment begins with dosage reduction or cessation of the offending agents when possible. Accurate diagnosis further guides treatment, especially when multiple movement subtypes are present. For each subtype of movement abnormality, there is a limited range of pharmacological treatments with variable efficacy, and treatment decisions are often based on analysis of risks and likely benefits. The relatively recent development of valbenazine and deutetrabenazine provides effective and safe interventions for tardive syndromes. It is hoped that new drug development, especially for antipsychotics, will focus on medications with reduced liability to cause drug-induced movement disorders.

Drugs for Treatment of Bipolar Disorder

CHAPTER 37

Lithium

Jorge Almeida, M.D., Ph.D.
David Spelber, M.D.
Tawny Smith, Pharm.D.

History and Discovery

After noting the sedating properties of lithium in animals, Cade (1949) first described the successful treatment of mania with lithium salts. The FDA approved lithium for the treatment of acute mania in 1970 and for the maintenance treatment of bipolar disorder 4 years later (Jefferson and Greist 1977). However, lithium did not enter the market easily in the United States. Pharmaceutical companies were reluctant to produce this inexpensive drug that they could not patent (Kline 1973). Lithium is available generically and is inexpensive, which, added to its effectiveness, has given it longevity among the psychopharmacological treatment options for bipolar disorder (Chisholm *et al.* 2005).

Structure-Activity Relations

Lithium is the lightest alkali metal and a monovalent cation, and it shares some properties with sodium, potassium, and calcium. It is the third element of the periodic table. Substitution of or competition with other cations may contribute to its effects (Baldessarini 1996; Ward *et al.* 1994).

Pharmacological Profile

Lithium is minimally protein bound, does not undergo biotransformation, and is eliminated by the kidneys (Kilts 2000). Its narrow therapeutic index necessitates careful drug monitoring. Lithium appears to affect multiple neurotransmitter systems (see "Neurotransmitter Effects" subsection under "Mechanism of Action"), and it alters second-messenger systems such as cyclic adenosine monophosphate and cyclic guanosine monophosphate (Ward *et al.* 1994).

Pharmacokinetics and Disposition

Lithium is available in multiple preparations, including lithium carbonate tablets and capsules, lithium citrate solution, and slow-release tablet formulations (Jefferson *et al.* 1983). Immediate-release lithium carbonate capsules are marketed in strengths of 150 mg, 300 mg, and 600 mg, whereas immediate-release lithium carbonate tablets are available in only a single strength of 300 mg. Lithium citrate oral solution is available at a concentration of 300 mg/5 mL, which is considered equivalent to the 300-mg lithium carbonate immediate-release tablets and capsules. The extended-release lithium carbonate tablet formulation is available in 300-mg and 450-mg strengths. Generic equivalent products are available for all of these formulations (West-Ward Pharmaceuticals 2018).

Lithium is absorbed from the gastrointestinal tract and is renally excreted unchanged within approximately 24 hours (Baldessarini 1996). Peak plasma concentrations are reached in 0.25-3.00 hours with the immediate-release preparations and in 2-6 hours with the extended-release formulation (Finley *et al.* 1995; West-Ward Pharmaceuticals 2018). Lithium is not protein bound and is evenly distributed in total body water space (Jermain *et al.* 1991). Lithium excretion is controlled by osmotic factors and is a function of renal sufficiency (Birch *et al.* 1980). Steady-state concentrations are achieved in 4-5 days (Keck and McElroy 2002).

Mechanism of Action

Despite extensive research, the exact mechanism of lithium's action as a mood stabilizer has yet to be elucidated. Multiple theories, based on animal models and on limited studies in humans, have been proposed. In the following pages we review theories centering on lithium's effects on various neurotransmitter systems, on intracellular second-messenger systems, and on signal transduction, as well as a unifying theory focused on lithium's neuroprotective effects.

Neurotransmitter Effects

Lithium brings about changes in several of the major neurotransmitter systems in the brain, with the overall effect being stimulation of inhibitory transmission and inhibition of excitatory signals (Malhi *et al.* 2013). Chronic administration of lithium in mice increases and stabilizes glutamate uptake. This modulatory action could, in part, explain lithium's antimanic effect because it results in overall reduction of an excitatory neurotransmitter (Dixon and Hokin 1998). Lithium also normalizes low cerebrospinal fluid (CSF) levels of GABA (an inhibitory neurotransmitter) in patients with bipolar disorder (Berrettini *et al.* 1983, 1986; Brambilla *et al.* 2003).

Lithium enhances norepinephrine and serotonin function in the CNS, which could explain its antidepressant effects (Price *et al.* 1990; Schildkraut *et al.* 1969; Stern *et al.* 1969). Of particular interest is lithium's confirmed antagonistic action at serotonin$_{1A}$ (5-HT$_{1A}$) and serotonin$_{1B}$ (5-HT$_{1B}$) autoreceptors (Haddjeri *et al.* 2000; Massot *et al.* 1999); such action would have the effect of increasing serotonin availability in the synaptic cleft (Shaldubina *et al.* 2001). Clinically, 5-HT$_{1A}$ receptors may be involved in alleviation of depression, and 5-HT$_{1B}$ receptors may play a role in the regulation of sleep, sensorimotor inhibition, and locomotor activity (Monti *et al.* 1995; Sipes and Geyer 1996).

Inositol Depletion

There has been much focus on the role of the inositol cycle in the clinical effects of lithium. Lithium is a noncompetitive inhibitor of inositol monophosphatase, depleting free inositol within 5 days of treatment initiation (Berridge *et al.* 1989). These changes last for 3-4 weeks after lithium is discontinued (Moore *et al.* 1999). Depletion of free inositol can lead to effects on neurotransmitter and intracellular second-messenger systems linked to the inositol cycle. For example, adrenergic, serotonergic, and cholinergic receptor subtypes are coupled to the cycle via G proteins, and the cycle in turn regulates protein kinase C action, which appears to be influenced by lithium treatment in mania (Hahn *et al.* 2005).

Of note, depression is associated with low CSF levels of inositol in humans (Barkai *et al.* 1978). Exogenous inositol can alleviate depression (Levine *et al.* 1995) and panic attacks (Benjamin *et al.* 1995). Belmaker *et al.* (1996) suggested a complex "pendulum" relationship between inositol and lithium that may provide a basis for understanding lithium's antimanic and antidepressant effects.

Glycogen Synthase Kinase Inhibition

Glycogen synthase kinase 3 (GSK-3) is an enzyme with direct involvement in gene transcription, synaptic plasticity, and cell structure (Malhi *et al.* 2013). Both lithium (Klein and Melton 1996; Li *et al.* 2007) and valproate inhibit GSK-3, suggesting that signaling pathways that converge in GSK-3 are important in bipolar disorder (G. Chen *et al.* 1999). GSK-3 is an inhibitor of the Wnt protein-signaling pathway, which affects neuronal signal transduction. Lithium thus would be predicted to mimic Wnt signaling (Phiel and Klein 2001). Wnt signaling triggers a cascade of events that lead to stimulation of protein kinase C activity (Williams and Harwood 2000). Thus, the actions of lithium on both the inositol cycle and the GSK-3 signaling pathway lead to a common effect on protein kinase C. Because this enzyme's activity has been reported to be elevated in bipolar disorder, protein kinase C inhibitors have been investigated for their potential treatment utility (Zarate and Manji 2009).

Neurotrophic and Neuroprotective Effects

A unifying theory posits that lithium's mechanism of action may be related to its neurotrophic and neuroprotective effects (Quiroz *et al.* 2010). Patients treated with lithium have larger cortical and hippocampal volumes (Hajek *et al.* 2012, 2014; Moore *et al.* 2000), and these effects are independent of treatment response (Hajek *et al.* 2014). One proposed mechanism is lithium's activation of the transcription factor cyclic adenosine monophosphate response element binding protein, which in turn increases the expression of brain-derived neurotrophic factor and the antiapoptotic B-cell lymphoma 2 proteins (Alda 2015; Quiroz *et al.* 2010). Another proposed mechanism is lithium's inhibition of GSK-3 and subsequent activation of the Akt neuroprotective pathway (Tajes *et al.* 2009).

Pharmacogenetics of Lithium Response in Bipolar Disorder

Pharmacogenetics of response to lithium is an important aspect of precision medicine aimed at predicting response and tolerability in bipolar disorder. Several reviews on the topic have been published (Cruceanu *et al.* 2009; Lin *et al.* 2021; McCarthy *et al.* 2010; Oedegaard *et al.* 2016; Serretti and Drago 2010; Smith *et al.* 2010; Vecera *et al.* 2021). Vecera *et al.* (2021), in their recent review, discussed six genomewide association studies that each included at least 250 subjects for statistical considerations. Genes regulating the glutamate system (e.g., *GADL1* and *GRIA2*) were associated with lithium response (Chen *et al.* 2014; Perlis *et al.* 2009). Moreover, the authors found that genetic risk for schizophrenia and major depressive disorder has an inverse relationship to lithium responses in bipolar disorder (Amare *et al.* 2018, 2021). A single-nucleotide polymorphism on *SESTD1* may be related to lithium's ability to permeate cell membranes and mediate autoimmune and renal effects (Song *et al.* 2016). Furthermore, epigenetics and stress regulation of long noncoding RNA genes and human leukocyte antigen (HLA) genes were associated with lithium response (Amare *et al.* 2018; Hou *et al.* 2016).

Precision medicine in bipolar disorder is still in its infancy, and replication in independent cohorts is necessary before it can be used in real-world clinical applications. Precision medicine for this indication is likely to include not only genetics but also other biomarkers, such as neuroimaging (Athey *et al.* 2021; Fleck *et al.* 2017; Rootes-Murdy *et al.* 2019), and epigenetic markers (Marie-Claire *et al.* 2020).

Indications and Efficacy

Immediate-release lithium dosage forms are indicated as monotherapy for the treatment of bipolar disorder. This indication includes treatment of acute manic and mixed episodes and maintenance treatment in patients ages 7 years and older (West-Ward Pharmaceuticals 2018). Extended-release lithium tablets are indicated for treatment of manic episodes and maintenance treatment in patients 12 years and older with a diagnosis of bipolar disorder (Glenmark Pharmaceuticals 2022).

Bipolar Disorder

Acute Mania

Cade (1949) first published data on the efficacy of lithium in mania. More than 70 years later, lithium remains one of the most efficacious treatments for bipolar disorder and, according to contemporary treatment guidelines, should be considered first for acute mania, with certain exceptions, such as presence of mixed features, comorbid substance use, or prior treatment nonresponse (Yatham *et al.* 2018).

Lithium versus placebo. Lithium has been shown in studies to be more efficacious than placebo in the treatment of acute mania (Bowden *et al.* 1994, 2005; Fountoulakis *et al.* 2012; Goodwin *et al.* 1969; Keck *et al.* 2009; Kushner *et al.* 2006; Poolsup *et al.* 2000; Schou *et al.* 1954; Smith *et* *al.* 2007; Yildiz *et al.* 2011). A review of response rates in randomized trials of medication treatment indicated that lithium was at least somewhat efficacious in the treatment of mania, with a response rate of 70% (87 of 124 patients) (Keck *et al.* 2000). A more recent review of pharmacological treatment of bipolar disorder (Baldessarini *et al.* 2019) demonstrated an overall response rate of 49.1% (95% CI: 42.8%-55.3%) for lithium in placebo-controlled trials in patients with acute mania, a rate similar to that for other treatment types.

Lithium versus antipsychotics. Early studies with lithium established its antimanic efficacy relative to first-generation (typical) antipsychotics (Johnson *et al.* 1968; Poolsup *et al.* 2000; Prien *et al.* 1972; Segal *et al.* 1998; Shopsin *et al.* 1975; Spring *et al.* 1970; Takahashi *et al.* 1975). A study by Prien *et al.* (1972) comparing lithium against chlorpromazine found that although chlorpromazine was more effective in reducing manic symptoms in severely ill patients, lithium also reduced symptoms while causing fewer side effects. However, a later meta-analysis concluded that lithium was more effective than chlorpromazine in acute mania (Poolsup *et al.* 2000). Segal *et al.* (1998) reported that hospitalized patients with acute mania responded equally well to lithium, haloperidol, and the second-generation agent risperidone.

Lithium has also been studied in comparison with second-generation antipsychotic medications (Berk *et al.* 1999; Bowden *et al.* 2005; Fountoulakis *et al.* 2012; Keck *et al.* 2009; Niufan *et al.* 2008; Poolsup *et al.* 2000; Segal *et al.* 1998; Smith *et al.* 2007; Yildiz *et al.* 2011). However, many of these trials were focused on assessing the efficacy of the antipsychotic in a noninferiority approach rather than on demonstrating significant differences between the medications. For example, in a direct comparison with lithium, olanzapine produced greater improvement in manic symptoms over a period of 4 weeks, but it also produced more weight gain (Niufan *et al.* 2008). By and large, antipsychotics appear to work faster than lithium but carry higher risks for weight gain and other metabolic effects (Fountoulakis *et al.* 2012; Yildiz *et al.* 2011). The addition of lithium to therapy with extended-release quetiapine was found to be more efficacious than add-on placebo (i.e., quetiapine monotherapy) for patients with bipolar mania (Bourin *et al.* 2014). A 2019 systematic review of lithium for acute mania (McKnight *et al.* 2019), which included 36 randomized controlled trials and 4,220 patients, found that lithium is not inferior to antipsychotics, although it may be less likely than olanzapine to induce a response (defined as 50% reduction in symptoms on the Young Mania Rating Scale); however, the quality of evidence supporting this finding was not high.

Lithium versus anticonvulsants. Double-blind randomized studies suggest that carbamazepine and lithium are equally effective in the treatment of acute mania (Fountoulakis *et al.* 2012; Lerer *et al.* 1987; Okuma *et al.* 1990; Poolsup *et al.* 2000; Small *et al.* 1991; Yildiz *et al.* 2011). In a direct comparison of lithium and divalproex, Bowden *et al.* (1994) demonstrated a similar advantage for both agents over placebo, with lithium and divalproex each achieving response in about 48% of patients over 3 weeks. A 12-week study of patients randomly assigned to open treatment with lithium or divalproex yielded additional evidence of the two agents' comparable efficacy

and tolerability over a longer-than-usual study period (Bowden *et al.* 2008, 2010a). Various meta-analyses and systematic reviews examining the efficacy of lithium, valproate, and carbamazepine in mania have shown no significant differences (Poolsup *et al.* 2000; McKnight *et al.* 2019).

Mixed States

The presence of mixed features--co-occurrence of depressive and manic symptoms--may predict a poorer response to lithium monotherapy. Freeman *et al.* (1992), in a direct comparison of lithium and valproate, showed that high pretreatment depressive symptom scores were associated with a favorable response to valproate (Fountoulakis *et al.* 2012). To further investigate the relation between co-occurring depressive symptoms and treatment response in acute mania, Swann *et al.* (1997) designed a parallel-group study of lithium versus divalproex and analyzed outcomes relative to the presence of a mixed affective state. They found that the presence of depressive symptoms during an acute manic episode was associated with a poorer response to lithium and a better response to divalproex. Existing reviews assessing the efficacy of treatment strategies for mixed states (McIntyre and Yoon 2012; Takeshima 2017) suggest combination therapy including atypical antipsychotics and conventional mood stabilizers such as lithium or valproate have the most replicated evidence; additional studies are needed to better understand lithium's degree of efficacy, and the high rate of attempted suicide in mixed states may make lithium a reasonable treatment option that should not be overlooked.

Psychotic Mania

Lithium is equally effective in psychotic and nonpsychotic mania, and early improvement in psychotic symptoms was found to predict higher remission and response rates (de Sousa *et al.* 2012).

Bipolar Depression

Lithium is considered a first-line treatment for acute bipolar depression (Compton and Nemeroff 2000; Yatham *et al.* 2018). Placebo-controlled trials showing the efficacy of lithium in bipolar depression include those by Baron *et al.* (1975), Donnelly *et al.* (1978), Fieve *et al.* (1968), Goodwin *et al.* (1969, 1972), Greenspan *et al.* (1970), and Noyes *et al.* (1974).

A meta-analytic summary of the above-listed short-term studies showed a significant advantage for lithium over placebo in bipolar disorder (Selle *et al.* 2014). In the Efficacy of Monotherapy Seroquel in BipOLar DEpressioN (EMBOLDEN) I study, in which in 802 patients were randomly assigned to 8 weeks of treatment with lithium (600-1,800 mg/day), quetiapine (300 mg/day or 600 mg/day), or placebo (Young *et al.* 2010), lithium failed to separate significantly from placebo on the main efficacy measure (Montgomery-Asberg Depression Rating Scale score); however, the study was powered to show an effect for quetiapine, and the mean serum level in lithium-treated subjects was low (0.6 mEq/L).

In the Bipolar CHOICE (Clinical Health Outcomes Initiative in Comparative Effectiveness) trial, 482 patients with bipolar I or II disorder, the majority (> 88%) of whom were experiencing depressive symptoms at study entry (Nierenberg *et al.* 2016), were randomly assigned to receive lithium plus adjunctive personalized treatment ($n = 240$) or quetiapine plus adjunctive personalized treatment ($n = 242$) for 6 months. In this study, which used new clinical trial methodology, participants in the lithium group were not given a second-generation antipsychotic, and those in the quetiapine group were not given lithium; however, other adjunctive treatments were provided in accordance with best-practice guidelines (Nierenberg *et al.* 2013). Both groups showed improvement, with 20% achieving sustained response over the study period, and no differences in outcome were detected between the lithium and quetiapine groups.

In the Lithium Treatment Moderate-Dose Use Study (LiTMUS; Nierenberg *et al.* 2013), 283 patients with bipolar I or II were randomly assigned to receive optimized personalized treatment (OPT; evidence-based, guideline-informed care) alone or OPT plus lithium at a moderate dosage. The lithium dosage was fixed at 600 mg/day for the first 2 months of the study but was allowed to change based on clinical need after that. Over the 6 months of the trial, the two groups had similar scores on clinical outcome measures, with a sustained remission rate of 27%. Although the addition of lithium conferred no advantage over OPT alone, fewer patients in the lithium-plus-OPT group than in the OPT-only group received second-generation antipsychotics.

Rapid Cycling

In 1974, Dunner and Fieve observed that patients with bipolar disorder who had not responded to long-term lithium prophylaxis were more likely to have had four or more mood episodes per year, giving rise to the belief that lithium is not effective in treating rapid cycling. However, subsequent studies have shown that rapid-cycling bipolar disorder responds poorly to most available treatments and that treatment with lithium does reduce the burden of illness. In a study examining lithium's efficacy in rapid-cycling bipolar disorder, Dunner *et al.* (1977) found that patients who had received lithium for at least 1 year had a higher percentage of "well time" relative to baseline and reported that their mood episodes were shorter and less severe. A long-term prospective study of open-label treatment with lithium found a higher rate of recurrence among rapid cyclers than non-rapid cyclers but similar improvement in symptoms and morbidity (as measured by percentage of time ill, episode frequency, and time to recurrence) (Baldessarini *et al.* 2000). Finally, a meta-analysis of clinical studies comparing subjects with rapid-cycling and non-rapid-cycling bipolar disorder showed that although lithium was less effective in preventing recurrence among rapid cyclers, it did have beneficial effects on severity and duration of episodes (Kupka *et al.* 2003). In a 20-month double-blind, parallel-group comparison study, Calabrese *et al.* (2005) evaluated lithium and divalproex monotherapy for maintenance treatment of rapid-cycling patients who had been stabilized on a combination of lithium and divalproex. The rates of relapse were similar for lithium-treated and divalproex-treated patients.

Prophylaxis and Maintenance

Prophylactic or maintenance therapy aims to prevent the recurrence of future depressive and hypomanic episodes. Lithium is considered a first-line treatment for this indication (Yatham *et al.* 2018).

Numerous systematic reviews and meta-analyses have synthesized the outcomes of placebo-controlled trials involving lithium for maintenance therapy and found lithium's efficacy in preventing relapse of mood episodes to be statistically significant,

with more protection afforded to prevention of mania than depression (Baldessarini *et al.* 2019; Beynon *et al.* 2009; Davis *et al.* 1999; Geddes *et al.* 2004).

Tondo *et al.* (1998a) found lithium to be effective in long-term use (> 1 year) in decreasing frequency of mood episodes and time ill in patients with bipolar I or bipolar II disorder. Benefits of lithium treatment were not significantly different among patients with psychotic or mixed episodes, rapid cycling, or more classic forms. There was no decrease in efficacy with long-term use. Despite finding evidence for lithium's efficacy, Kulhara *et al.* (1999) noted that only 24% of the patients followed in a lithium clinic remained free of mood episodes while receiving lithium prophylaxis (average duration of monitoring: 11 years). Treatment nonadherence or subtherapeutic lithium serum levels (< 0.4 mEq/L), high numbers of psychosocial stressors, higher numbers of depressive episodes before lithium treatment, and poor social support predicted poorer response to lithium prophylaxis. In contrast, starting lithium early in the course of illness predicted a better response to treatment ($P < 0.001$), after episode polarity, sex, age at onset, duration of illness, and duration of lithium prophylaxis were accounted for (Franchini *et al.* 1999).

Bowden *et al.* (2003) compared the efficacy of lamotrigine, lithium, and placebo in preventing relapse to mood episodes among subjects with bipolar I and a recent manic or hypomanic episode. After completing a stabilization phase during which treatment with lamotrigine was initiated and other medications were discontinued, subjects were randomly assigned to one of the three drug groups and followed for 18 months. Both lithium and lamotrigine were superior to placebo in prolonging the time to any mood episode, with lithium predominantly effective against manic, hypomanic, and mixed episodes and lamotrigine predominantly effective against depressive episodes. A similar study in subjects with bipolar I and a recent depressive episode (Calabrese *et al.* 2003) reported the same findings. A post hoc analysis of the two studies revealed that lithium not only prolonged the time between random assignment and onset of subsyndromal symptoms but also prolonged the time between onset of subsyndromal symptoms and emergence of the full mood episode (Frye *et al.* 2006). In a study by Weisler *et al.* (2011), subjects with bipolar disorder who had been stabilized on quetiapine were randomly assigned to continue quetiapine or be switched to lithium or placebo for up to 104 weeks. Both lithium and quetiapine were superior to placebo in prevention of manic and depressive episodes.

The Bipolar Affective Disorder: Lithium/Anticonvulsant Evaluation (BALANCE) study examined the effects of lithium monotherapy, valproate monotherapy, or lithium-plus-valproate combination therapy for relapse prevention in a large international cohort (BALANCE Investigators and Collaborators 2010). More than 300 patients with bipolar I disorder initially completed a "run-in" phase during which they took both lithium and valproate. Of those who tolerated the combination, a subsequent randomization phase assigned subjects to lithium alone, valproate alone, or continued combination treatment for up to 2 years of follow-up. The primary outcome measure was time to new intervention (either medication change or hospitalization) for an emerging mood episode. The study results showed that the combination of lithium and valproate was superior to valproate alone and suggested that lithium monotherapy was superior to valproate monotherapy. However, the apparent discrepancy between these findings and the conclusions of Bowden *et al.* (2010a) may reflect differences in the population studied, the outcome measures used, or a suboptimal valproate dosage in the BALANCE

study. In a double-blind, randomized maintenance trial of lithium versus olanzapine, individuals with bipolar disorder experiencing mixed or manic symptoms first received open-label cotreatment with lithium and olanzapine (Tohen *et al.* 2005). Those whose symptoms remitted were then randomly assigned to monotherapy with either lithium or olanzapine for 52 weeks. Recurrence rates were similar for the two groups, with 38.8% of patients on lithium and 30.0% of those on olanzapine experiencing a relapse. Whereas the two drugs were comparable in prevention of depressive episodes, olanzapine was more effective than lithium in prevention of manic and mixed episodes.

Maintenance dosing. Once-daily dosing of lithium at bedtime yields higher brain-to-serum ratios of lithium levels compared with twice-daily dosing schedules (Soares *et al.* 2001). Investigators have observed substantial variations in brain lithium levels among people with similar serum lithium levels (Gonzalez *et al.* 1993). In a study evaluating maintenance treatment with lithium at dosages yielding low (0.4-0.6 mEq/L) versus standard (0.8-1.0 mEq/L) serum levels, Gelenberg *et al.* (1989) found that the risk of relapse was 2.6 times higher in patients randomly assigned to maintenance lithium at the low serum level. However, in a reanalysis of the data (Perlis *et al.* 2002), the higher relapse rate observed with the low serum level was found to be associated with the abrupt reduction in lithium dosage that occurred after randomization in patients who were switched from the standard range to the low range. Thus, an abrupt reduction in lithium dosage may negatively affect the course of illness.

Nolen and Weisler (2013) conducted a post hoc analysis of a double-blind trial of patients with bipolar disorder who were stabilized on quetiapine after a manic, depressive, or mixed episode and then randomly assigned to continue quetiapine or be switched to lithium or placebo for up to 104 weeks. Times to recurrence of any mood episode, as well as to recurrence of a manic or a depressive episode, were longer for patients with serum lithium levels of 0.6-1.2 mEq/L than for patients with serum lithium levels less than 0.6 mEq/L. No difference in time to recurrence was found between patients receiving placebo and patients with lithium levels lower than 0.6 mEq/L, providing evidence that maintenance lithium dosages should be high enough to achieve a plasma level of at least 0.6 mEq/L for prevention of mania and depressive episodes in bipolar disorder. In a similar post hoc analysis by Severus *et al.* (2010), subjects were first stabilized on a combination of lithium and olanzapine and then randomly assigned to lithium (at dosages aimed at achieving low [0.6 mEq/L)], medium [0.6-0.79 mEq/L], or high [> 0.8 mEq/L] serum levels) or olanzapine (10 mg/day or 10-20 mg/day) for the maintenance phase. The low-serum-level lithium group had a significantly higher risk of relapse to manic or mixed--but not to depressive--episodes compared with the medium-and high-serum-level lithium groups and had a higher risk of depression than the 10-20 mg/day olanzapine group. These findings provide further evidence that lithium levels should be higher than 0.6 mEq/L for optimal protection against relapse to manic, mixed, or depressive episodes.

Unipolar Depression (Major Depressive Disorder)

An analysis of five controlled trials of lithium augmentation of antidepressant treatment for patients with unipolar depression found significant improvement in 56%-96% of patients (Austin *et al.* 1991; Carvalho *et al.* 2009; Heit and Nemeroff 1998;

Heninger *et al.* 1983; Kantor *et al.* 1986; Schopf *et al.* 1989; Stein and Bernadt 1993; Zusky *et al.* 1988). Two separate meta-analyses of randomized, double-blind, placebo-controlled trials in unipolar and bipolar depression evaluated lithium's efficacy in augmenting and accelerating clinical response to antidepressant treatment (Crossley and Bauer 2007). Although there was firm evidence of lithium's efficacy as an augmentation agent, there was only modest evidence of its efficacy in accelerating response to antidepressants. Concordant with previous reviews (Abou-Saleh *et al.* 2017; Bauer *et al.* 2010; Nelson *et al.* 2014), a recent systematic review (Undurraga *et al.* 2019) and selective random-effects meta-analysis of 12 randomized controlled trials of lithium augmentation of antidepressants for acute unipolar major depressive disorder found a highly significant pooled outcome (OR: 2.34; 95% CI: 1.57-3.51; $P < 0.0001$) favoring lithium over placebo, with even more robust effect in studies involving treatment-resistant depression, despite the fact that only 4 out of the 12 trials found significant efficacy for lithium on an individual basis.

In treatment-refractory depression, open-label data support the addition of lithium to antidepressants, including tricyclic antidepressants, trazodone, and selective serotonin reuptake inhibitors (SSRIs) (Bschor *et al.* 2001; De Montigny *et al.* 1981, 1983, 1985; Dinan 1993; Fontaine *et al.* 1991; Price *et al.* 1986). Double-blind and open-label studies support the use of lithium for augmentation of tricyclic antidepressants, monoamine oxidase inhibitors, trazodone, mirtazapine, and SSRIs (Baumann *et al.* 1996; Fava *et al.* 1994; Heninger *et al.* 1983; Joffe *et al.* 1993; Kantor *et al.* 1986; Katona *et al.* 1995; Nierenberg *et al.* 2006; Schopf *et al.* 1989; Schule *et al.* 2009; Zusky *et al.* 1988). In the large Sequenced Treatment Alternatives to Relieve Depression multisite trial, 15.9% of subjects who did not experience remission with citalopram monotherapy and another medication trial achieved remission after the addition of lithium (Nierenberg *et al.* 2006).

Single studies have found that severe depression (Bschor *et al.* 2013), weight loss and psychomotor retardation (Alvarez *et al.* 1997), more than three lifetime major depressive episodes, and a family history of major depressive or bipolar disorder in a first-degree relative (Sugawara *et al.* 2010) may predict a good response to lithium augmentation in treatment-resistant depression. These studies are limited by small heterogeneous samples, variations in treatment duration, use of mostly nonblinded, retrospective study designs, and absence of a placebo comparator.

Timing of onset of lithium action when the drug is used as an adjunct to antidepressant treatment remains unclear. A meta-analysis of placebo-controlled trials of lithium augmentation in treatment-resistant depression found that a minimum lithium dosage of 800 mg/day (or dosing to produce a serum level of [?] 0.5 mEq/L) and a treatment duration of at least 2 weeks favored lithium augmentation as compared with placebo (Bauer and Dopfmer 1999).

Suicide: Is Lithium Protective?

Tondo *et al.* (2021) estimated that up to 60% of people living with bipolar disorder attempt suicide during their lifetime, and suicide fatalities occur in 5%-20% of adults with bipolar disorder. Meta-analyses of studies of lithium treatment in major mood disorders (Baldessarini *et al.* 2006; Cipriani *et al.* 2013; Guzzetta *et al.* 2007; Tondo *et al.* 1998b, 2001) found significantly lower suicide risk for subjects who were receiving treatment with lithium. A meta-review by Smith and Cipriani (2017) identified 16 systematic reviews and meta-analyses published since 2001 of lithium and suicide rates in major mood disorders, which despite some methodological concerns and heterogeneity among studies overwhelmingly support the antisuicidal effects of lithium. Yet specific, placebo-controlled conditions in randomized trials designed to investigate the effects of lithium treatment on suicidality are sparse, in part for various ethical, practical, and financial reasons (Tondo and Baldessarini 2018). The low event rate of suicide is a barrier to conducting adequately powered trials; however, several large-scale observational studies have found a reduced incidence of completed suicide among individuals on lithium treatment, consistent with the evidence from existing randomized data (Roberts *et al.* 2017).

Abrupt discontinuation of lithium treatment is associated with increased rates of suicidal behavior. The antisuicidal effect of lithium appears to be independent of its mood-stabilizing actions (Tondo *et al.* 2021).

A systematic review by Del Matto *et al.* (2020) included 16 ecological studies, 11 of which found a significant inverse association between levels of lithium in drinking water and suicide rates, supporting the growing evidence that routine consumption of lithium in tap water may have antisuicidal effects in the general population.

Use in Special Populations

Children and Adolescents

Lithium is FDA approved for the treatment of bipolar disorder in adolescents and has been shown to be significantly more efficacious than placebo for both bipolar disorder and substance abuse in this population, but not for major depressive disorder (Findling *et al.* 2015; Geller *et al.* 1998a, 1998b; Ryan *et al.* 1999). Lithium had a large effect size in an open-label study of acute manic or mixed episodes in children and adolescents (Kowatch *et al.* 2000) and in an open-label study of acute depressive episodes in adolescents with bipolar I disorder (Patel *et al.* 2006), and it had a medium effect size in a randomized, placebo-controlled study of acute manic or mixed episodes in children and adolescents with bipolar I disorder (Findling *et al.* 2015). In a randomized, double-blind maintenance trial of lithium versus divalproex in children and adolescents ages 5-17 years (Findling *et al.* 2005), lithium-treated patients and divalproex-treated patients did not differ in time to relapse. However, in the Treatment of Early Age Mania study, risperidone was more effective than lithium or divalproex in children ages 6-15 years, whereas there was no difference in efficacy between lithium and divalproex. The incidence of metabolic side effects was higher with risperidone than with lithium, but the discontinuation rate was higher with lithium than with risperidone (Geller *et al.* 2012).

Older Adults

Lithium has shown effectiveness in older adults. In a retrospective trial, significantly more patients age 55 years or older improved with lithium than with valproate, especially in cases of classic mania, whereas the two drugs had similar response rates when the analysis considered only cases of mixed mania (S. T. Chen *et al.* 1999). The lithium serum level range associated with improvement in older adults was similar

to the therapeutic range in younger adults: [?] 0.8 mEq/L (other studies recommend a target dosage [?] 0.4 mEq/L [Nolen *et al.* 2019; Yatham *et al.* 2018]).

Medical comorbidity may be a particular consideration for older adults. Volume depletion, use of nonsteroidal anti-inflammatory drugs (NSAIDs), or use of thiazide diuretics can increase lithium levels (Stoudemire *et al.* 1990). The lithium dosage needed to achieve therapeutic serum concentrations decreases threefold from middle to old age, with this trend continuing into the ninth and tenth decades of life (Rej *et al.* 2014b). In a population-based retrospective cohort study involving 1,388 patients with bipolar disorder ages 66 years and older, medical hospitalizations, 1-year acute medical health utilization outcomes, and medical comorbidity rates were not different between lithium users and valproate users or lithium/valproate nonusers at 1-year follow-up (Rej *et al.* 2015).

Meta-analyses show that lithium is associated with increased risk of reduced urinary concentrating ability, but there is little evidence for a clinically significant reduction in renal function in most patients, and the risk of end-stage renal failure is low (McKnight *et al.* 2012). In one study, lithium use was associated with an increased risk of renal failure among adults ages 50 years and above (Rej *et al.* 2014a). However, chronic lithium use at lower dosages did not affect renal function in older adults with mild cognitive impairment and dementia over a 4-year study period (Aprahamian *et al.* 2014). Because lithium is cleared almost exclusively by the kidneys, patients with end-stage renal disease undergoing hemodialysis cannot eliminate lithium other than through dialysis. Lithium should be given only after a dialysis treatment and need not be given daily (Stoudemire *et al.* 1990).

Because lithium appears to have neuroprotective effects that may reduce oxidative damage, its potential role in prevention of neurocognitive decline in aging and prevention of Alzheimer's disease has been suggested (Mohammadianinejad *et al.* 2014; Shao *et al.* 2005; Tsaltas *et al.* 2007;

Yoshida *et al.* 2006). A Danish study that followed more than 4,800 patients with newly diagnosed bipolar disorder over 10 years found that long-term treatment with lithium, but not with other psychopharmacological agents, was associated with a reduced risk of developing dementia (Kessing *et al.* 2010). A study that analyzed data from a national health insurance database in Taiwan concluded that lithium use was significantly related to a reduced risk of stroke in patients with bipolar disorder. The association between lithium use and reduced stroke risk was strongest for patients who received the highest lithium dosages, experienced the longest durations of lithium treatment, and had the highest rates of lithium exposure (Lan *et al.* 2015).

Pregnant or Lactating Women and Their Children

The risks of lithium treatment during pregnancy and lactation must be carefully weighed against the risks of untreated bipolar disorder. It was once thought that pregnancy may provide a protective effect for new or worsening bipolar disorder; however, a longitudinal study of 89 women with bipolar disorder conducted by Viguera *et al.* (2007b) reported an overall recurrence risk of 71% during pregnancy, with the risk of recurrence two times greater among women who discontinued mood stabilizer treatment compared with those who did not. Those who discontinued the mood stabilizer also spent a larger percentage of their pregnancy ill (43%) compared with those who continued (9%). This is important because women with undertreated or untreated bipolar disorder

are thought to be at increased risk for perinatal complications and poor pregnancy outcomes (Jablensky *et al.* 2005; Lee and Lin 2010; Poels *et al.* 2018).

Although it is not generally thought that pregnancy elevates the relapse risk of bipolar episodes, the postpartum period, especially the first 3 months, is a particularly vulnerable time for relapse (Viguera *et al.* 2000; Wesseloo *et al.* 2016). A meta-analysis conducted by Wesseloo *et al.* (2016) found that the overall risk of postpartum relapse was 37% in women with a history of bipolar disorder. Women who continued medications during pregnancy were significantly less likely to experience a relapse in the postpartum period (23%) than those who discontinued medications (66%). Similarly, those who used mood-stabilizing medications during the postpartum period were also at lower risk of relapse (29%) than those who did not (65%). This high risk of recurrence has prompted experts in the field to recommend postpartum prophylactic treatment with a mood stabilizer for women with bipolar disorder (Wesseloo *et al.* 2016). It is important to highlight that lithium was the primary mood stabilizer used in the studies, leading the authors of the meta-analysis to emphasize that prophylactic lithium reduces the risk of bipolar recurrence during pregnancy and the postpartum period (Wesseloo *et al.* 2016).

Although prophylactic use of lithium during pregnancy may confer a lower risk of mood episode recurrence when compared with other mood stabilizers, it is not without other risks (Viguera *et al.* 2007a). Lithium freely crosses the placenta barrier, with maternal and fetal levels equilibrating (Newport *et al.* 2005). Several studies suggest that lithium exposure during pregnancy may elevate the risk of miscarriage, especially with first trimester exposure (Diav-Citrin *et al.* 2014; Fornaro *et al.* 2020; Poels *et al.* 2020). Newport *et al.* (2005) reported that lithium-exposed neonates were more likely than nonexposed neonates to be born preterm, to have lower birthweights, and to have longer hospital stays. However, a more recent meta-analysis of six international cohort studies concluded that lithium use during pregnancy did not elevate the risk of preterm birth, low birthweight, or small size for gestational age but was associated with a higher risk for admission to a neonatal special care unit compared with the mood disorder reference group (Munk-Olsen *et al.* 2018). In the same meta-analysis, lithium did not elevate the risk of preeclampsia, gestational diabetes, cesarean section, or postpartum hemorrhage.

Regarding teratogenic risk, data suggest that lithium exposure during pregnancy is less harmful than experts previously believed (Cohen *et al.* 1994). In fact, although the overall risk of Ebstein's anomaly--a rare cardiac malformation with an incidence of 1 in 20,000 live births--may be higher with lithium use (relative risk of 10-20 times that in the general population) than without, the absolute risk associated with first-trimester lithium exposure is thought to be 0.05%-0.1% (Cohen and Rosenbaum 1998). Three more recent investigations (Fornaro *et al.* 2020; Munk-Olsen *et al.* 2018; Patorno *et al.* 2017) reported higher rates of major malformations with lithium exposure when compared with the unexposed groups, but only two reported higher rates of cardiac malformations with first trimester lithium exposure (Fornaro *et al.* 2020; Patorno *et al.* 2017). Overall, lithium is not a high-risk teratogen, and the risk of cardiovascular anomalies with lithium is substantially lower than the risk of neural tube defects associated with some anticonvulsants used for mood stabilization.

Lithium exposure has been associated with neonatal adverse effects, such as hypoglycemia, nephrogenic diabetes insipidus, thyroid dysfunction, and neonatal lithium

toxicity (Poels *et al.* 2018). In the previously discussed study conducted by Newport *et al.* (2005), birth complications were directly correlated with higher placental lithium concentrations (> 0.64 mEq/L). In contrast, a more recent retrospective observational study did not find this correlation (Molenaar *et al.* 2021). Some experts recommend a dosage reduction or a brief suspension (24-48 hours) of lithium therapy before delivery to minimize neonatal complications (Graham *et al.* 2018; Molenaar *et al.* 2021; Newport *et al.* 2005). However, there is a lack of evidence supporting this practice. In contrast, other experts cite concern for elevated postpartum decompensation with lithium dosage reductions and instead recommend vigilant monitoring of lithium levels during labor and the first 2 weeks postpartum (Molenaar *et al.* 2021; Wesseloo *et al.* 2017).

Lithium is secreted in breast milk and is passed on to the infant in clinically significant levels (relative infant dose of 10% or greater). In a study of 10 mother-infant pairs, serum lithium levels in the infants ranged from 0.09 to 0.3 mEq/L (mean 0.16 mEq/L). Transient elevations in infant thyroid-stimulating hormone, blood urea nitrogen, and creatinine levels were observed without evident long-term effects (Viguera *et al.* 2007a). The study authors concluded that breastfeeding in the context of lithium therapy may be considered reasonable for a healthy infant when the mother's bipolar disorder is clinically stable, lithium monotherapy or a simple medication regimen is being used, and the pediatrician is supportive of the mother's breastfeeding while she is being treated with lithium. The American Academy of Pediatrics no longer considers the use of lithium a contraindication to breastfeeding and currently recommends that in addition to receiving counseling about the benefits of breastfeeding, parents be informed of the potential risks for infants exposed to clinically significant lithium levels and cautioned that the long-term effects of this exposure are unknown (Sachs and Committee on Drugs 2013).

Side Effects and Toxicology

Laboratory Monitoring

Before lithium therapy is started, a medical history should be obtained, as well as baseline renal laboratory tests (blood urea nitrogen, creatinine level, estimated glomerular filtration rate), thyroid function tests, a pregnancy test for women of childbearing age, and an electrocardiogram (ECG) for individuals older than 40 years (American Psychiatric Association 2002; McKnight *et al.* 2012; Yatham *et al.* 2018). The American Psychiatric Association practice guideline for the treatment of bipolar disorder suggests that renal function should be assessed every 2-3 months and thyroid function should be tested once or twice during the first 6 months of treatment. After the first 6 months, renal laboratory tests, thyroid function tests, and calcium should be monitored every 6-12 months or as clinically indicated (American Psychiatric Association 2002; McKnight *et al.* 2012; Shine *et al.* 2015; Yatham *et al.* 2018). Additionally, it is recommended that the lithium serum concentration be measured 5 days after the most recent dosage titration and then every 3-6 months or more frequently as clinically indicated (Yatham *et al.* 2018). Levels should be drawn approximately 12 hours after the last dose regardless of formulation (Yatham *et al.* 2018).

Central Nervous System

Cognitive Side Effects

Cognitive side effects have been reported to be among the more disturbing side effects experienced by patients receiving lithium maintenance treatment and are associated with self-reported nonadherence (Gitlin *et al.* 1989; Johnson *et al.* 2007). Patients may report feeling cognitively "dull." Although they are commonly reported, it is often challenging to determine whether the cognitive changes are due to the lithium itself, the general nature of bipolar disorder, residual symptoms, or the presence of comorbid psychiatric or medical conditions (Paterson and Parker 2017). Although research on the impact of lithium on several different cognitive domains, such as executive functioning and memory, has resulted in inconclusive findings, lithium does not appear to affect attention (Paterson and Parker 2017; Sabater *et al.* 2016). In fact, one study suggests that lithium may improve neurocognitive functioning (Burdick *et al.* 2020). In addition, data supporting the potential neuroprotective effects of lithium are growing. Long-term lithium treatment has been associated with elevated hippocampal volumes (Pfennig *et al.* 2014). This finding might explain how lithium may preserve memory and learning (Sabater *et al.* 2016).

Neurotoxicity

Neurotoxicity, delirium, and encephalopathy have been reported with lithium use. Specific populations with underlying neurological vulnerability have been noted to be at higher risk. Also, certain circumstances, such as concomitant electroconvulsive therapy or use of other psychotropics--especially first-generation antipsychotics--have been found to increase the risk of neurotoxic adverse effects from lithium treatment.

Neurotoxic reactions are potentially irreversible. Permanent neurological deficits reported after episodes of lithium intoxication (Apte and Langston 1983; Donaldson and Cuningham 1983) have included deficits in recent memory, ataxia, and movement disorders. Early hemodialysis may help prevent permanent sequelae in these cases. Donaldson and Cuningham (1983) also reported persistent neurological sequelae of lithium toxicity involving multiple sites within the nervous system. In a case series of 90 patients, Adityanjee *et al.* (2005) reported that the most common sequela in the syndrome of irreversible lithium-effectuated neurotoxicity was cerebellar dysfunction. The other typical neurological signs of this syndrome include extrapyramidal symptoms, brain stem dysfunction, and dementia (Ivkovic and Stern 2014).

Himmelhoch *et al.* (1980) found a greater incidence of lithium-induced neurotoxicity in older adults. Other risk factors include longer duration of exposure to higher lithium levels and presence of medical comorbidities, including nephrogenic diabetes insipidus, abnormal thyroid function and impaired renal function, preexisting neurological disease, and drug combinations including antipsychotics (Ivkovic and Stern 2014; Netto and Phutane 2012; Oakley *et al.* 2001).

Tremor

Postural tremor is one of the most commonly reported lithium side effects, with an estimated incidence of approximately 25% (reported range between 4% to 65%) (Gelenberg and Jefferson 1996). It generally appears early in treatment but may appear at any time. It is typically symmetrical and indistinguishable from an essential tremor. A severe or coarse tremor may indicate toxicity. Lithium-induced tremor can be managed by maintaining lithium levels at the lower end of the therapeutic range or by reducing or eliminating additive factors, such as caffeine intake. If lowering the dosage is not possible or is ineffective, an antidote, such as a beta-blocker, may be helpful in managing a debilitating tremor (Baek *et al.* 2014).

Metabolic Abnormalities

Thyroid Abnormalities

Lithium has been associated with the development of goiter, hypothyroidism, and, more rarely, hyperthyroidism (Czarnywojtek *et al.* 2020). In a chart review of 135 patients who underwent maintenance treatment with lithium, 38% had abnormal values on thyroid function tests (thyroid-stimulating hormone or free thyroxine index), with an association between laboratory abnormalities and length of time on lithium (Fagiolini *et al.* 2006). In a systematic review and meta-analysis, McKnight *et al.* (2012) reported that in comparison with placebo-treated subjects, lithium-treated patients had a sixfold higher risk of clinical hypothyroidism and showed higher levels of thyroid-stimulating hormone. In a retrospective study of 209 individuals who received lithium, Kirov (1998) found that 14.9% of the female patients and 3.4% of the male patients developed hypothyroidism. Reports have suggested that subclinical hypothyroidism during lithium therapy is even more common (Kleiner *et al.* 1999; Lombardi *et al.* 1993).

Lithium-induced hypothyroidism (LIT) can appear early in treatment but is generally associated with chronic use, with an average lithium treatment duration of 18 months before a hypothyroidism diagnosis (Kibirige *et al.* 2013). Risk factors for LIT include the presence of antithyroid antibodies (Bocchetta *et al.* 2007), female gender (Kirov 1998; Shine *et al.* 2015), age greater than 50 (Kirov 1998; Shine *et al.* 2015), and family history of hypothyroidism (Kusalic and Engelsmann 1999). Development of LIT does not necessitate lithium discontinuation and can be addressed by initiating thyroid supplementation. Although the reversibility of LIT is not well established, a recent retrospective cohort study by Lieber *et al.* (2020) reported successful discontinuation of the thyroid replacement after lithium discontinuation in 29 of 35 patients, suggesting it may be reversible for some patients.

Parathyroid Abnormalities

Chronic lithium exposure has been associated with hypercalcemia and hyperparathyroidism (Mifsud *et al.* 2020). Although reported prevalence rates vary, it is estimated that approximately one-quarter of lithium-treated patients experience hypercalcemia while taking lithium (Meehan *et al.* 2018). A meta-analysis by McKnight *et al.* (2012) found that lithium-treated patients demonstrated a 10% absolute risk of developing lithium-induced hyperparathyroidism, compared to 0.1% of the general population. Similar increases in parathyroid hormone (Albert *et al.* 2013) and calcium (Albert *et al.* 2013; Hayes *et al.* 2016; Shine *et al.* 2015) in lithium-treated patients have been reported in other studies as well. Monitoring of calcium levels at baseline and yearly, or more frequently in the presence of clinical symptoms, is suggested (McKnight *et al.* 2012; Shine *et al.* 2015).

Weight Gain

Weight gain is a commonly reported side effect of lithium. In one double-blind trial, the average weight change over 1 year was 4.2 kg (Calabrese *et al.* 2003). Along with lithium's cognitive side effects, weight gain is often cited by patients as a reason for treatment nonadherence (Gitlin *et al.* 1989; Johnson *et al.* 2007). Lithium has been associated with clinically significant weight gain (> 7%) (McKnight *et al.* 2012), which may pose a greater risk for patients who are obese before commencement of lithium treatment compared with those who are at normal weight (Bowden *et al.* 2006).

Renal Complications

Lithium has multiple renal effects, including those that occur early in treatment and those that occur with chronic use. Lithium can induce tubular dysfunction early in treatment, with reduced urinary concentrating capacity developing over the first 8 weeks of treatment. Nephrogenic diabetes insipidus occurs in 20%-87% of patients on lithium (Azab *et al.* 2015; Markowitz *et al.* 2000; Stone 1999). These effects may be partially mediated by lithium's action on water and sodium channels in the kidney (Grunfeld and Rossier 2009); thus, there has been renewed interest in using amiloride, a sodium channel-blocking diuretic, in an attempt to modify lithium's toxicity (Azab *et al.* 2015; Bedford *et al.* 2008).

Another important renal effect of lithium is chronic kidney disease, which tends to occur after 10-20 years of lithium treatment (Presne *et al.* 2003) at an estimated prevalence of 1.2% (Bendz *et al.* 2010) to 21% (Lepkifker *et al.* 2004), depending on the definition of renal insufficiency used. However, the risk of progressing to end-stage renal disease is small (0.5%-1%) (Bendz *et al.* 2010; Tredget *et al.* 2010). The clearest risk factors are duration of lithium use (Bendz *et al.* 2010; Bocchetta *et al.* 2015; Castro *et al.* 2016; Presne *et al.* 2003), dosing of lithium more than once a day (Castro *et al.* 2016), and higher serum lithium levels (Castro *et al.* 2016; Shine *et al.* 2015); additional possible risk factors are older age (Bendz *et al.* 2010; Bocchetta *et al.* 2015; Castro *et al.* 2016; Close *et al.* 2014; Presne *et al.* 2003), female sex (Castro *et al.* 2016; Shine *et al.* 2015), previous episodes of lithium toxicity, and presence of comorbid disorders (Castro *et al.* 2016; Lepkifker *et al.* 2004). The potential for chronic renal disease is the reason that close laboratory monitoring is required for patients on long-term lithium treatment (Shine *et al.* 2015). Once-daily dosing and maintaining low lithium levels when possible may be helpful in preventing long-term renal damage (Castro *et al.* 2016; Malhi and Tanious 2011). The decision of whether to stop lithium in the setting of renal impairment must be made collaboratively by the patient, the psychiatrist, and the nephrologist. Chronic kidney disease can progress to renal failure even after lithium is stopped; however, with mild or moderate renal dysfunction, there may be improvement if a change is made (Grunfeld and Rossier 2009).

Cardiac Changes

Lithium has been associated with a wide range of cardiac effects, ranging from benign electrocardiographic changes to fatal arrhythmias. Lithium intoxication (levels > 1.5 mEq/L) has been reported to cause cardiac alterations, including sinus bradycardia, sinus node dysfunction, and QTc prolongation (Mehta and Vannozzi 2017; Steckler 1994). T-wave changes, as well as ventricular irritability, may occur with lithium treatment

(Altinbas *et al.* 2014; Mitchell and Mackenzie 1982). T-wave depression (flattening, rounding, notching, and inversion) is the most commonly reported ECG change during chronic lithium therapy (Mehta and Vannozzi 2017). Chronic lithium use has also been associated with atrioventricular block (Martin and Piascik 1985) and sinus node dysfunction (Rosenqvist *et al.* 1993). Additionally, a Brugada pattern ECG (J point elevation, coved ST segment, and T-wave inversion) has been reported with lithium use, with an incidence of approximately 0.5% (Darbar *et al.* 2005; Yap *et al.* 2009). Although lithium does not appear to have a direct effect on blood pressure, elevated systolic blood pressure has been associated with lithium-induced ECG changes (Chen *et al.* 2020). Because of the potential risk of cardiac effects, careful monitoring of the pulse and electrocardiographic monitoring are recommended for patients older than 40 years and those with underlying cardiac disease (Chen *et al.* 2020; Roose *et al.* 1979; Tilkian *et al.* 1976).

Cutaneous Changes

Lithium is associated with a variety of cutaneous conditions, most frequently acne and psoriasis but also eczema, hair loss, hidradenitis suppurativa, nail dystrophy, and mucosal lesions. Prevalence estimates for adverse cutaneous effects in lithium-treated patients are as high as 45%. Most cases can be managed without lithium discontinuation; however, these adverse effects can be distressing to patients and may affect medication compliance (Yeung and Chan 2004).

Drug-Drug Interactions

Lithium With Other Mood Stabilizers

Lithium With Anticonvulsants

Lithium is commonly used in combination with other mood stabilizers, and although such combinations can be synergistic, polypharmacy may increase the risk of adverse reactions (Freeman and Stoll 1998; Lenox *et al.* 1996). The combination of lithium and valproate is often used in refractory mania. Interactions may include additive side effects, such as sedation, tremor, or weight gain, but the pharmacokinetics of lithium are not altered by the addition of valproate (Granneman *et al.* 1996). Lithium and carbamazepine have been combined for bipolar disorder refractory to lithium alone, but this combination may increase the risk of neurotoxicity (Chaudhry and Waters 1983; Kishimoto 1992; Shukla *et al.* 1984, 1985; Small *et al.* 1995). There are inconsistent reports about interactions between lithium and lamotrigine; whereas Chen *et al.* (2000) found no significant alterations in the pharmacokinetics of lithium in 20 healthy volunteers, another study showed that cotreatment with lithium may lower the serum concentration of lamotrigine (Reimers *et al.* 2005). Topiramate (Bialer *et al.* 2004), gabapentin (Frye *et al.* 1998; Vollmer *et al.* 1986), and benzodiazepines (Adler 1986; Modell *et al.* 1985; Sachs *et al.* 1990a, 1990b) exhibit no pharmacokinetic interactions with lithium.

Lithium With Antipsychotics

Although many investigators have reported safe and efficacious results from the concomitant use of lithium and antipsychotics for the treatment of bipolar disorder, the combination has been associated with increased risk of acute and irreversible neurotoxicity (including delirium, neuroleptic malignant syndrome, acute dyskinesias, and tardive dyskinesia) (Blake *et al.* 1992; Chen and Cardasis 1996; Cohen and Cohen 1974; de Leon and Spina 2018; Netto *et al.* 2019). Considering that lithium and antipsychotics are commonly prescribed together without incident, neurotoxicity is probably a rare phenomenon. Prospective data suggest that lithium can be combined with antipsychotics for acute mania without expected impact on the pharmacokinetics of either drug (Boulton *et al.* 2012; Bowden *et al.* 2010b; Chiu *et al.* 2014; Madhusoodanan *et al.* 2000; Szegedi *et al.* 2012). On the other hand, the use of clozapine with lithium should be done cautiously because the combination has been associated with CNS abnormalities including myoclonus, seizures, and electroencephalographic abnormalities (Kitagawa *et al.* 2021).

Lithium With Antidepressants

Lithium is often used concomitantly with antidepressants in the treatment of bipolar depression and refractory unipolar depression. In general, antidepressants are not thought to affect lithium pharmacokinetics (Sitsen *et al.* 2000; Troy *et al.* 1996). However, serotonin syndrome--a constellation of mental status and behavioral changes (either agitation or sedation), motor symptoms (restlessness, weakness, hyperreflexia, or ataxia), and autonomic dysfunction (nausea or vomiting, dizziness, sweating, fever)--has been reported with the use of lithium and serotonergic antidepressants (Adan-Manes *et al.* 2006; Fagiolini *et al.* 2001; Shahani 2012). In contrast, a retrospective study conducted by Bauer *et al.* (1996) found no increase in serotonergic adverse effects. Similarly, in an extensive review of systematic reports, Hawley *et al.* (2000) were unable to identify serious or lethal toxicities with the combined use of SSRIs and lithium.

Lithium With Nonpsychotropic Medications

NSAIDs, including cyclooxygenase 2 inhibitors, increase the risk of lithium toxicity by decreasing lithium clearance (Grandjean and Aubry 2009; Phelan *et al.* 2003). Because of the unpredictability of this interaction, it is generally best to advise patients on lithium to avoid NSAIDs, if possible. Although high-dose NSAID use has been associated with acute kidney injury in older adults and long-term NSAID use has been associated with the development of chronic kidney disease (Zhang *et al.* 2017), it is unclear whether the combination of lithium and an NSAID puts patients at an elevated risk of developing acute kidney injury or chronic kidney disease. Regardless, when lithium is used concurrently with NSAIDs, signs and symptoms of toxicity, lithium levels, and renal function should be monitored more diligently.

Because lithium excretion relies on renal clearance, diuretic medications may affect lithium levels, depending on their site of action. Thiazide diuretics trigger a compensatory increase in reabsorption in the proximal tubule and lead to elevations in lithium levels, whereas loop diuretics do not promote lithium reabsorption and do not greatly affect lithium levels (Finley *et al.* 1995). Osmotic diuretics increase lithium excretion and may counteract lithium toxicity, and either no change or a slight increase in lithium levels has been reported with potassium-sparing diuretics.

Neurotoxic and other adverse reactions have been associated with the concomitant administration of lithium with calcium channel blockers (Dubovsky *et al.* 1987; Finley *et al.* 1995; Wright and Jarrett 1991). Angiotensin converting enzyme inhibitors or angiotensin receptor 1 blockers may raise lithium levels (Finley *et al.* 1996). Serum lithium levels may increase in the context of sodium restriction (Bennett 1997). Lactulose may result in lithium toxicity, possibly by volume depletion, as reported in a case series (Bregman *et al.* 2014). On the other hand, theophylline and caffeine can decrease lithium concentrations (Cook *et al.* 1985). Importantly, if either is discontinued, lithium clearance may decrease, resulting in an increase in lithium concentration (Jefferson 1988).

Conclusion

Lithium is an important option in the evidence-based rational treatment of bipolar disorder. Bipolar disorder affects between 1% and 5% of the population (Akiskal *et al.* 2000) and causes significant morbidity and mortality, and the diagnosis of bipolar disorder carries a high risk for suicide. A summary published in 1990 estimated that 25%-50% of individuals with bipolar disorder attempt suicide and 19% complete suicide (Goodwin *et al.* 2007).

Lithium has been shown to be effective for acute mania and bipolar depression and as a prophylactic treatment for bipolar disorder. Some data suggest that conditions such as comorbid neurological illness and mixed episodes may be indicators of illness that is more responsive to mood stabilizers other than lithium. Evidence also suggests that lithium can play a role in the treatment of refractory unipolar depression for patients at risk for suicide. Lithium may be less risky than anticonvulsants in pregnancy. However, a 20-year trend in pharmacological choice in bipolar disorder in the outpatient setting in a nationally representative dataset shows an approximately 13% decrease in lithium use and an increase of approximately 39% in second-generation antipsychotic use (Rhee *et al.* 2020). Although we continually seek new treatments and hope that they will be more efficacious and better tolerated than older medications, lithium remains a strong first-line treatment option despite being discovered over 70 years ago, the only example of such longevity in psychiatry.

CHAPTER 38

Valproate

Robert M. A. Hirschfeld, M.D.[++]

Charles L. Bowden, M.D.[++++]

History and Discovery

Valproate was the first mood stabilizer to be studied as an alternative to lithium (Lambert *et al.* 1966). An enteric-coated formulation, divalproex sodium, was approved in the United States for the treatment of mania in 1995. An extended-release (ER) formulation of divalproex was approved for migraine in 2001 and for mania in 2006. Valproate, both as divalproex and as other formulations, is now approved worldwide for the treatment of mania. Valproate sodium injection is an antiepileptic drug indicated as an intravenous alternative for patients in whom oral administration of valproate products is temporarily not feasible (Hospira 2013).

Pharmacological Profile

Valproic acid (dipropylacetic acid) (Figure 38-1 is an eight-carbon branched-chain carboxylic acid that is structurally distinct from other antiepileptic and psychotropic compounds (Bocci and Beretta 1976; Levy 1984). Its three-dimensional structure overlays that of naturally occurring fatty acids (e.g., oleic and linolenic acids). Valproate binds in a saturable manner to the neuronal membrane sites to which these longer-chain fatty acids attach. Some of valproate's molecular mechanisms are probably a consequence of this physiochemical property.

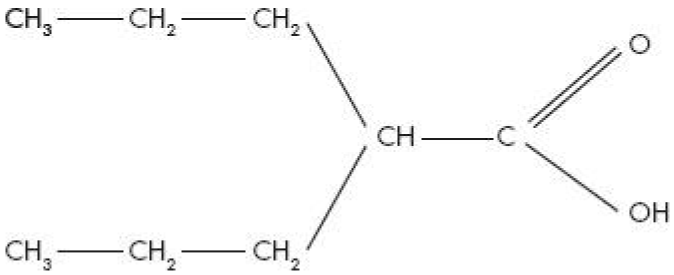

FIGURE 38-1. Chemical structure of valproic acid.

Pharmacokinetics and Disposition

Valproate is commercially available in the United States in five oral preparations: divalproex sodium (an enteric-coated, stable-coordination compound containing equal proportions of valproic acid and valproate sodium in a 1:1 molar ratio) delayed-release tablet (AbbVie Inc. 2023a); valproic acid capsule and syrup (Abbott Laboratories 2009); valproate sodium injection (Hospira 2013); divalproex sodium sprinkle capsule (containing coated particles of divalproex sodium), which can be ingested intact or pulled apart for contents to be sprinkled on food (AbbVie Inc. 2023c); and a divalproex sodium ER tablet that provides once-daily dosing and a substantially flatter peak-to-trough ratio (AbbVie Inc. 2023b) (Table 38-1). Sodium valproate for intravenous injection has been demonstrated to provide a reduction in manic symptoms within 1 day or less (Grunze *et al.* 1999). In addition, valproate sodium can be compounded in suppository form for rectal administration, and diluted valproate sodium solution can also be administered rectally. The valproate ion is the common compound in plasma.

TABLE 38-1. Valproic acid dosage forms

Active ingredient	Dosage form/ route of administration	Strength/therapeutic equivalence
Divalproex sodium		
	Capsule, delayed-release pellets; oral	Eq 125 mg valproic acid
	Tablet, delayed release; oral	Eq 125 mg valproic acid
	Tablet, delayed release; oral	Eq 250 mg valproic acid
	Tablet, delayed release; oral	Eq 500 mg valproic acid
	Tablet, extended release; oral	Eq 250 mg valproic acid
	Tablet, extended release; oral	Eq 500 mg valproic acid
Valproic acid		
	Capsule; oral	250 mg
	Syrup; oral	250 mg/5 mL
Valproate sodium		
	Injectable; injection	Eq 100 mg base/mL

Source. Data from U.S. Food and Drug Administration 2023.

The bioavailability of valproate approaches 100% with all preparations (Wilder 1992). With the exception of divalproex sodium, all preparations taken orally are rapidly absorbed. Sodium valproate and valproic acid attain peak serum concentrations within 2 hours. Divalproex sodium reaches peak serum concentrations in 3-8 hours (AbbVie Inc. 2023a). In comparison with the delayed-release tablets, the ER form of divalproex sodium has an earlier onset of absorption and an approximately 20% smaller difference between trough and peak serum levels (AbbVie Inc. 2023b) (Figure 38-2).

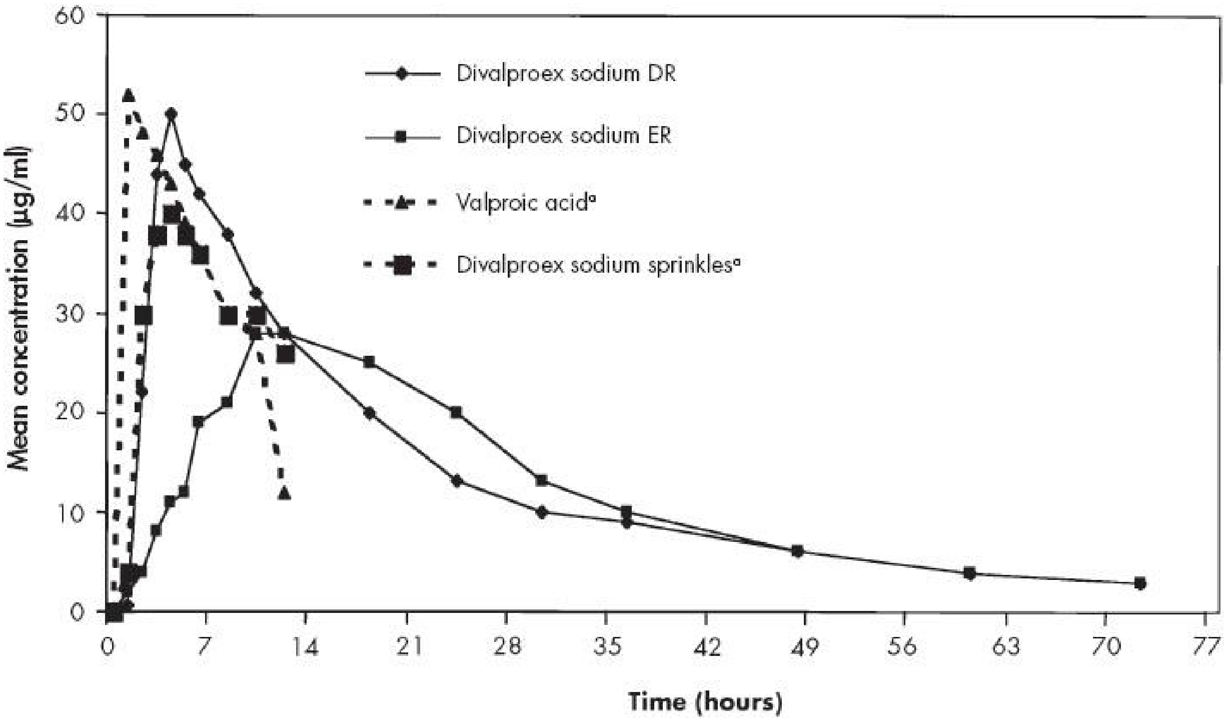

FIGURE 38-2. Mean plasma valproate concentrations with different formulations.

DR = delayed-release; ER = extended-release.

[a]Data derived from different studies after 500-mg doses.

Source. Abbott Laboratories, data on file.

Valproate is highly protein bound, predominantly to serum albumin and proportional to the albumin concentration. Although patients with low levels of albumin have a higher fraction of unbound drug, the steady-state level of total drug is not altered. Only the unbound drug crosses the blood-brain barrier and is bioactive. Thus, when valproate is displaced from protein-binding sites through drug interactions, the total drug concentration may not change; however, the pharmacologically active unbound drug does increase and may produce signs and symptoms of toxicity. Moreover, when the plasma concentration of valproate rises in response to dosage increases, the amount of unbound (active) valproate increases disproportionately and is metabolized, with an apparent increase in clearance of total drug, yielding lower-than-expected total plasma concentrations (Levy 1984; Wilder 1992) (Figure 38-3). In addition, protein binding of valproate is increased by low-fat diets and decreased by high-fat diets. Because of lower serum protein levels, women and older adults generally have a higher proportion of the active free moiety.

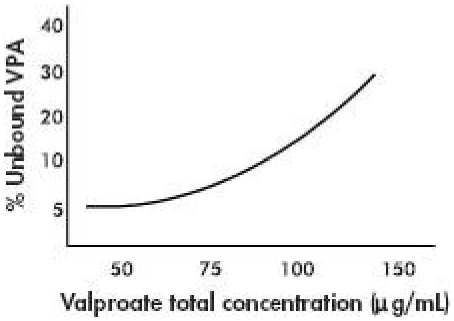

FIGURE 38-3. Total valproate (VPA) concentrations in the presence of dosage increases.

As the total concentration of valproate increases, protein-binding sites become saturated, and the percentage of unbound to bound valproate increases.

Source. Adapted from Figure 4 (p. 66S) in Wilder BJ: "Pharmacokinetics of Valproate and Carbamazepine." *Journal of Clinical Psychopharmacology* 12(1 Suppl):64S-68S, 1992. Copyright (c) 1992, Williams & Wilkins. Used with permission.

The concentration range needed for good clinical effect in mania is approximately 45-125 mg/mL (Bowden *et al.* 1996). Patients who are able to tolerate higher serum levels--up to about 125 mg/mL--may experience greater improvement (Allen *et al.* 2006). Patients with rapid cycling in the context of bipolar II disorder or cyclothymic disorder may respond to serum valproate concentrations of less than 50 mg/mL (Jacobsen 1993). In maintenance treatment, patients whose serum valproate levels were maintained between 75 mg/mL and 99 mg/mL had superior outcomes compared with patients whose serum levels were either lower or higher than this range (Keck *et al.* 2005). Valproate is metabolized in the liver, primarily through glucuronidation.

When used for the treatment of bipolar disorder, valproate is usually begun at a dosage of 15-20 mg/kg/day. The drug can be orally loaded at 20-30 mg/kg/day for patients with acute mania to induce a more rapid response (Hirschfeld *et al.* 2003). The dosage of valproate is increased according to the patient's response and tolerance of side effects, usually by 250-500 mg/day every 1-3 days, to serum concentrations of 45-125 mg/mL. Of note, sedation, increased appetite, and reductions in white blood cell counts and platelet counts all become more common at serum concentrations greater than 100 mg/mL (Bowden *et al.* 2000).

Mechanism of Action

Valproate stimulates extracellular signal-regulated kinase and indirectly inhibits glycogen synthase kinase 3 (Cournoyer and Desrosiers 2009). Valproate also stimulates the activity of Bcl-2, a neuroprotective substance (Gray *et al.* 2003). Valproate inhibits histone deacetylase, and many of the drug's subcellular effects (e.g., increasing brain-derived neurotrophic factor) are probably a consequence of this action (Harwood and Agam 2003; Perova *et al.* 2010).

Indications and Efficacy

Acute Mania in Bipolar Disorder

Valproate is an effective treatment for acute mania in adults. Its efficacy in this population is slightly less than that of olanzapine and indistinguishable from that of lithium (Bowden 2011; Marcus *et al.* 2011; Muller-Oerlinghausen *et al.* 2000; Tohen *et al.* 2002; Yatham *et al.* 2003). Valproate has been studied in adjunctive regimens with various antipsychotics, with findings consistently pointing to greater efficacy for combination treatment than for monotherapy (Bowden 2011; Marcus *et al.* 2011; Muller-Oerlinghausen *et al.* 2000; Tohen *et al.* 2002; Yatham *et al.* 2003).

Valproate has been studied in combination with an atypical antipsychotic in patients with an inadequate response to lithium or valproate monotherapy (Tohen *et al.* 2002). The combination was more effective than monotherapy plus placebo. In a similar study, adding either risperidone or haloperidol for patients inadequately responding to valproate monotherapy was more effective than monotherapy plus placebo (Sachs *et al.* 2002). These findings suggest that adding an antipsychotic to the treatment of patients inadequately responding to valproate monotherapy is effective.

Few studies of any antimanic agent have addressed its effectiveness in hypomanic episodes, which are more common than manic episodes, even in patients with bipolar I disorder. In an 8-week randomized, double-blind, placebo-controlled study of outpatients with bipolar and related disorders manifesting hypomanic symptoms, divalproex ER was significantly more effective than placebo in reducing hypomanic or mild manic symptoms ($P = 0.024$) (McElroy *et al.* 2010).

Acute Depression in Bipolar Disorder

Four small (total sample in all studies: 140) double-blind, placebo-controlled 8-week studies of divalproex have been conducted (Davis *et al.* 2005; Ghaemi *et al.* 2007; Muzina *et al.* 2011; Sachs *et al.* 2001). Three of the four studies reported positive results, and there was a trend favoring divalproex in the fourth (Sachs *et al.* 2001).

Maintenance Treatment of Bipolar Disorder

One large double-blind, placebo-controlled maintenance study of valproate monotherapy has been published (Bowden *et al.* 2000). Patients who recovered with open treatment with either divalproex or lithium, had satisfactory lithium or valproate blood levels, and were in remission for at least 2 weeks were randomly assigned to maintenance treatment with divalproex, lithium, or placebo. Neither the divalproex group nor the lithium group differed significantly from the placebo group on time to any mood episode. The rate of relapse to mania with placebo was lower than anticipated. Among the subset of patients who received divalproex in the open acute phase, those randomly assigned to continue on divalproex in the double-blind maintenance phase had significantly longer times to recurrence of any mood episode or a depressive episode (Bowden *et al.* 2000).

Maintenance studies of combination treatment with quetiapine were much more revealing of efficacy. Two studies with identical designs (Suppes *et al.* 2009; Vieta *et al.* 2008) enrolled patients with bipolar disorder and either a depressed or a manic episode who had been successfully treated with a combination of quetiapine and either lithium or divalproex and who had been in remission for at least 12 weeks. Patients were randomly assigned to either continue on the quetiapine and lithium/divalproex combination or receive lithium/divalproex and a placebo and were followed for 2 years. The patients treated with lithium/divalproex and placebo were more than twice as likely as those receiving the combined treatment to relapse into either a manic or a depressive episode.

Mania Secondary to Head Trauma or Neurodevelopmental and Neurodegenerative Disorders

Evidence suggesting that secondary or complicated mania responds well to valproate is mixed. In an open study of 56 valproate-treated patients with mania, response was associated with the presence of nonparoxysmal abnormalities on the electroencephalogram but not with neurological soft signs or abnormalities on computed axial tomography scans of brain (McElroy *et al.* 1988). A study from the 1980s (Pope *et al.* 1988) suggested that manic patients who had experienced a closed-head injury before the onset of bipolar disorder were more likely to respond successfully to valproate treatment for mood symptoms.

Agitation and Clinical Decline in Older Adults With Dementia

Patients with dementia are often institutionalized for agitation and behavioral disturbances. In a randomized, blinded study in which 56 nursing home residents with agitation and dementia received either placebo or individualized doses of divalproex, the drug-placebo difference on Brief Psychiatric Rating Scale Agitation scores significantly favored divalproex. Side effects occurred in 68% of the divalproex group and 33% of the placebo group and were generally rated as mild (Porsteinsson *et al.* 2001). Six weeks of open continuation treatment resulted in further decreases in agitation. Divalproex serum levels were greater than 40 mg/mL in both the acute blinded phase and the open continuation phase (Porsteinsson *et al.* 2003). Patients with dementia should generally receive valproate dosages lower than 1,000 mg/day to ensure adequate tolerability (Profenno *et al.* 2005). A small randomized, placebo-controlled study of valproate in the treatment of aggression in dementia failed to find any difference between valproate and placebo, although the fixed dosage used (valproate 480 mg/day) may have been inadequate (Sival *et al.* 2002).

Valproate also was studied for its potential utility in preventing or delaying illness progression in 313 nursing home residents with moderate Alzheimer's disease who had not yet experienced agitation or psychosis. Time to emergence of clinically significant agitation or psychosis did not differ between the valproate and placebo groups, and valproate was associated with serious adverse effects in the patients (Tariot *et al.* 2011). Taken in the aggregate, these studies suggest that although valproate at low dosages can decrease dementia-related agitation in some patients, valproate has no utility in slowing or preventing disease progression in Alzheimer's dementia.

Irritability and Aggression

Valproate has been reported to be effective in reducing irritability and aggression among diverse patient populations, including patients with autism spectrum disorders or personality disorders. In a 12-week double-blind study of children and adolescents with autism spectrum disorders, irritability measures were significantly improved with divalproex compared with placebo. Overall, 62% of the divalproex-treated subjects and 9% of the placebo subjects (OR, 16.7) were responders (Hollander *et al.* 2010).

In a randomized, placebo-controlled, double-blind study, 249 patients with Cluster B personality disorders, intermittent explosive disorder, or posttraumatic stress disorder were treated for 12 weeks with either divalproex or placebo. Although divalproex did not separate from placebo in the combined analysis of all patient groups, aggression and irritability scores among the 96 Cluster B patients showed significant improvement over the course of the study (Hollander *et al.* 2003).

Cotherapy in Schizophrenia

In a 4-week randomized, double-blind study, 242 patients with schizophrenia were assigned to receive either monotherapy with an antipsychotic (risperidone or olanzapine) or adjunctive treatment with divalproex plus the antipsychotic drug. Compared with participants receiving monotherapy, those who received combination therapy showed significantly greater improvement on Positive and Negative Syndrome Scale-Total and Positive and Negative Syndrome Scale positive symptom subscale scores from day 3 through day 21 but not at day 28. Platelet counts decreased with combination therapy (Casey *et al.* 2003).

Bipolar Disorder With Comorbid Alcohol Use Disorder

Bipolar disorder is often associated with substance use disorders, particularly alcoholism. In a prospective, blinded, placebo-controlled study, 59 patients with bipolar I disorder and DSM-IV (American Psychiatric Association 1994) alcohol dependence were treated with lithium carbonate and psychosocial interventions for 24 weeks, with half randomly assigned to receive adjunctive valproate. The addition of valproate was associated with significantly fewer heavy drinking days, fewer drinks per heavy drinking day, and fewer drinks per drinking day. Higher serum valproate concentrations were correlated with improved alcohol use outcomes. Both manic and depressive symptoms improved equivalently (Salloum *et al.* 2005).

In a 12-week double-blind, placebo-controlled trial, divalproex treatment was associated with a significantly reduced rate of relapse to heavy drinking; however, no significant differences were found in other alcohol-related outcomes. Significantly greater decreases in irritability were found in the divalproex-treated group than in the placebo-treated group, but no significant between-group differences were seen on measures of impulsivity (Brady *et al.* 2002).

Mixed Mania as a Potential Predictor of Positive Response to Valproate Versus Lithium

Patients with mixed manic presentations experienced greater symptom improvement with divalproex than with lithium treatment in two randomized studies (Freeman *et al.* 1992; Swann *et al.* 1997), one of which (Swann *et al.* 1997) was placebo controlled (reviewed in Bowden 2003). Patients with mixed manic symptoms and patients with pure manic symptoms showed equivalent improvement with divalproex (Swann *et al.* 1997). By contrast, during maintenance treatment patients with mixed mania had equivalent responses to divalproex and lithium, with evidence of higher rates of adverse effects as a function of the illness features of mixed mania, compared with rates of adverse effects in patients with euphoric mania (Bowden *et al.* 2005; Singh *et al.* 2013). These results suggest that effective long-term management of mixed manic states may require medication regimens that are more complex than monotherapy (Bowden 1995).

Side Effects and Toxicology

Valproate has FDA-mandated black box warnings for hepatotoxicity, fetal risk (including major congenital malformations, particularly neural tube defects), and pancreatitis. These potential adverse effects are discussed in the appropriate sections that follow (Murru *et al.* 2015).

Gastrointestinal Effects

Common gastrointestinal effects of valproate include nausea, vomiting, diarrhea, dyspepsia, and anorexia. These effects are dose dependent, are usually encountered at the start of treatment, and are often transient (DeVane 2003). Immediate-release formulations of valproic acid are more likely than ER and enteric-coated formulations of divalproex sodium to cause adverse events (Horne and Cunanan 2003; Zarate *et al.* 1999).

Tremor

Tremor consequent to valproate use resembles benign essential tremor and may respond to a reduction in dosage. Use of the ER or enteric-coated formulation may lessen the frequency of tremor (Wilder 1992; Zarate *et al.* 1999). Beta blockers, such as propranolol, are often helpful in reducing tremor.

Sedation

Mild sedation is common at initiation of valproate treatment. This adverse effect is dosage dependent and may be minimized by dosage reduction, slower titration, use of ER formulations, or taking all medication at bedtime.

Pancreatitis

Idiosyncratic acute pancreatitis is a rare but serious adverse event associated with valproate. Pancreatitis may occur at any point during treatment. It manifests as abdominal pain, nausea, vomiting, or anorexia. If these symptoms occur, the patient should immediately discontinue the medication and alert the doctor.

Hematological Effects

Leukopenia and thrombocytopenia are directly related to higher valproate serum levels, usually 100 mg/mL or greater (Acharya and Bussel 1996; Bowden *et al.* 2000). Thrombocytopenia is usually mild and rarely associated with bleeding complications. Management consists of dosage reduction. Platelet counts below 75,000/mm^3 should be monitored and regularly reassessed, because counts lower than this level are more frequently associated with bruising or bleeding (Zarate *et al.* 1999).

Hepatotoxicity

The risk of liver toxicity from valproate is largely limited to individuals younger than 2 years, whose hepatic function is still immature (Tohen *et al.* 2003). These effects usually occur within the first 6 months of treatment. Concurrent administration of other anticonvulsants increases the risk. Hepatotoxicity may manifest as weakness, lethargy, facial edema, anorexia, vomiting, and seizures. Obtaining liver function measures at baseline and monitoring them frequently during the first 6 months of treatment is essential.

Divalproex sodium is contraindicated for patients with hereditary neurometabolic syndromes caused by mitochondrial DNA polymerase gamma gene mutations and related disorders (AbbVie Inc. 2023a)

Weight Gain

Weight gain of 1.36-10.9 kg is seen in 3%-20% of patients taking valproic acid for periods ranging from 3 to 12 months (Bowden 2003). Weight gain has been consistently less with valproate than with olanzapine in comparison studies (1.22 kg vs. 2.79 kg) (Tohen *et al.* 2003; Zajecka *et al.* 2002). Valproate serum levels greater than 125 mg/mL are more likely than lower levels to be associated with weight gain (Bowden 2000). If increased appetite and weight gain occur with valproate, the dosage should be lowered as long as clinical effectiveness is maintained; alternatively, valproate should be discontinued and replaced with a regimen without risk of weight gain.

Cognitive Effects

Valproate infrequently produces adverse effects on cognitive functioning, and, conversely, it improves cognition in some patients (Prevey *et al.* 1996).

In a 20-week randomized, observer-blinded, parallel-group investigation, the addition of valproate to carbamazepine resulted in improvement in short-term verbal memory (Aldenkamp *et al.* 2000). No adverse cognitive effects associated with use of valproate were seen in a group of older adults (mean age 77 years) (Craig and Tallis 1994).

Lipid Profile Effects

Several studies indicate that valproate significantly reduces total and low-density lipoprotein cholesterol levels and increases high-density lipoprotein cholesterol levels in long-term treatment (Geller *et al.* 2012), and that it may protect against the adverse effects of some antipsychotic drugs on lipid function (Bowden *et al.* 2000; Casey *et al.* 2003; Tohen *et al.* 2003). A 3-week study of valproate in mania indicated reductions in cholesterol, high-density lipoprotein, and low-density lipoprotein compared with placebo and reported the effect to be limited to subjects who had total cholesterol levels of 200 mg/dL or greater at study entry (Bowden *et al.* 2006).

Polycystic Ovary Syndrome

Women taking valproate have a slightly higher frequency of polycystic ovary syndrome (PCOS) compared with women taking with other medications (Bilo and Meo 2008). PCOS is characterized by hyperandrogenism, irregular menstruation, and obesity. Obesity may be a mechanistic pathway whereby valproate (and potentially other drugs) predisposes women to PCOS. It is advisable to treat weight gain as a risk factor for possible development of PCOS and to intervene as needed to avoid clinically significant weight gain (Bilo and Meo 2008).

Hair Loss

Hair loss may occur early in treatment and is usually transient. Frequency of hair loss may be greater in women than in men (Lajee and Parsonage 1980). Dosage reduction and separation of valproate dosing from meals can be helpful in controlling this effect; supplemental zinc and selenium ingestion via multivitamin tablets also may be useful.

Use During Pregnancy and Lactation

Teratogenic Effects

Valproate is associated with an increased incidence of birth defects, including neural tube defects, craniofacial anomalies, limb abnormalities, and cardiovascular anomalies, especially if exposure to valproic acid occurs in the first 10 weeks of gestation (Kinrys *et al.* 2003; Samren *et al.* 1997). Neural tube defects, the most serious of the congenital anomalies, occur in 1%-4% of such infants. The risk of malformations is increased with higher dosages and higher serum levels of valproate and with concomitant use of other anticonvulsants (Anmella *et al.* 2019).

Developmental Effects

Exposure to valproate in utero is associated with a high risk (up to 40%) of developing serious neurodevelopmental disorders in childhood. These disorders include cognitive impairments, growth restriction, and behavioral abnormalities.

Because of the increased risk of teratogenic and developmental effects, women of childbearing age should use valproate only in extreme circumstances. Some regulatory agencies have banned its use altogether in this population (Anmella *et al.* 2019).

Overdose

Recovery from overdose-induced coma has occurred with serum valproate concentrations greater than 2,000 mg/mL. In addition, serum valproate concentrations have been reduced by hemodialysis and hemoperfusion, and valproate-induced coma has been reversed with naloxone (Rimmer and Richens 1985).

Drug-Drug Interactions

Because valproate is highly protein bound and extensively metabolized by the liver, a number of potential interactions may occur with other protein-bound or extensively metabolized drugs (Fogel 1988; Rimmer and Richens 1985). Thus, free fraction concentrations of valproate in serum can be increased, and valproate toxicity can be precipitated, by coadministration of other highly protein-bound drugs (e.g., aspirin) that can displace valproate from its protein-binding sites.

In the context of coadministration, valproate's competitive inhibition of lamotrigine excretion via glucuronidation requires that lamotrigine be started at a lower dosage--usually 25 mg every other day--with increases implemented cautiously. Lamotrigine's steady-state plasma concentrations are also generally lower when the drug is used with valproate, although not in all patients.

Conclusion

Valproate's broad spectrum of efficacy in bipolar and related disorders and generally good tolerability make it an important treatment option for patients with bipolar disorder. For optimal results, most patients should be treated with the formulation that permits once-daily dosing and has the lowest peak-to-trough serum level, which in the United States currently is divalproex ER. Although onset of action of valproate occurs quickly with use of loading-dose strategies, gradual dosage titration is the preferred method of treatment initiation for most manic patients. Medication tolerability is of paramount importance in fostering patient adherence to long-term treatment regimens.

During maintenance treatment, it is often necessary to reduce the dosage if adverse effects occur. Valproate is principally effective in and prophylactic for manic symptoms, although its prophylactic benefits in depression have been demonstrated. A history of multiple affective episodes or a current presentation characterized by irritability may be a particularly strong indicator of a favorable response to valproate. Although some patients may achieve acute and sustained remission with valproate monotherapy, many patients are more effectively treated with combinations, including other mood stabilizers and adjunctive medications. All current medications with established or putative roles in bipolar disorder can be combined with valproate.

CHAPTER 39

Carbamazepine, Oxcarbazepine, and Eslicarbazepine

Robert M. Post, M.D.
Po W. Wang, M.D.
Terence A. Ketter, M.D.

Pharmacotherapy of bipolar disorders is complex and rapidly evolving. Antipsychotics, antidepressants, anxiolytics, and new-generation anticonvulsants are commonly combined with traditional first-line mood stabilizers (lithium, valproate, carbamazepine) in clinical settings (American Psychiatric Association 2002; Ketter 2005; Suppes *et al.* 2005). Clinicians are challenged with integrating complex data regarding efficacy and adverse-effect profiles with pharmacological properties in their efforts to provide safe, effective, state-of-the-art pharmacotherapy for patients with bipolar disorder.

In this chapter, we review the pharmacology of carbamazepine and its analog oxcarbazepine. In the past, carbamazepine was considered an alternative to lithium and valproate rather than a first-line intervention in the treatment of bipolar disorder (American Psychiatric Association 2002), largely owing to methodological limitations of early studies of efficacy in bipolar disorder, complexity of use as a result of adverse effects and drug-drug interactions, and an initial lack of an FDA indication for the treatment of bipolar disorder. Carbamazepine received an FDA indication for the treatment of acute manic and mixed episodes in bipolar disorder following the publication of evidence from two randomized double-blind, placebo-controlled, parallel-group studies in patients with bipolar disorder (Weisler *et al.* 2004, 2005). Importantly, carbamazepine and oxcarbazepine may offer favorable efficacy and tolerability--in particular, less weight gain and fewer metabolic problems--for selected patients and thus can be important treatment alternatives (Akiskal *et al.* 2005). Likewise, the active monohydride metabolite of oxcarbazepine, licarbazepine, and its prodrug, the marketed product eslicarbazepine acetate, have good tolerability, although evidence of their efficacy in bipolar disorder is lacking.

History and Discovery

As one of the first alternatives to lithium and first-generation antipsychotics to become available, carbamazepine has played an important role in the development of therapeutic interventions for bipolar disorder (Post *et al.* 2007). Carbamazepine was developed in 1957 by J. R. Geigy AG in Europe, and its efficacy was established for epilepsy and paroxysmal pain by the 1960s and for bipolar disorder by the early 1970s (Takezaki and Hanaoka 1971). In the 1970s, acute mania was managed primarily with lithium and first-generation antipsychotics. Lithium was dramatically effective for patients with classical euphoric mania but was less effective for individuals with mixed or dysphoric mania, rapid cycling, a higher number of previous episodes, mood-incongruent delusions, or concurrent substance use disorders (Ketter and Wang 2002). Furthermore, starting treatment with lithium with a slow initial dosage titration meant that there was often a substantial delay before the medication's beneficial effects were experienced.

Limitations of lithium and first-generation antipsychotics led investigators to explore other treatment options for bipolar disorder. On the basis of early reports of favorable psychotropic profiles in patients with epilepsy and preliminary observations in subjects with mood disorders, systematic investigations of carbamazepine (Ballenger and Post 1978) and valproate commenced, and these anticonvulsants emerged as effective in acute mania. Carbamazepine and valproate were used off-label for bipolar disorder in the 1980s and early 1990s, respectively. The carbamazepine analog oxcarbazepine was anecdotally reported as useful in bipolar disorder in the 1980s (Muller and Stoll 1984), but it was not marketed in the United States for the treatment of epilepsy until 2000.

Because of economic concerns such as patent protection limitations and the high cost of obtaining FDA approval, a carbamazepine indication for bipolar disorder was not initially sought in the United States. A proprietary carbamazepine beaded extended-release capsule formulation (Equetro) received an FDA indication for the treatment of acute manic and mixed episodes in patients with bipolar disorder in late 2004.

Oxcarbazepine was approved for the treatment of epilepsy in the United States in 2000, following the development of several new anticonvulsants in the 1990s. Those anticonvulsants have heterogeneous psychotropic profiles (Ketter *et al.* 2003). Only the older drug phenytoin (Mishory *et al.* 2000) and oxcarbazepine (Emrich 1990) appear to be effective thus far in controlled (albeit small) trials in acute mania, and lamotrigine seems to be effective in acute and maintenance treatment of bipolar depression. FDA approval has not been sought for oxcarbazepine in the treatment of acute mania in the United States. On the basis of its greater ease of use, some clinicians consider oxcarbazepine to be an alternative to carbamazepine (American Psychiatric Association 2002). However, oxcarbazepine use remains limited by the lack of adequate data supporting its efficacy in bipolar disorder.

Licarbazepine, the active monohydroxy metabolite of oxcarbazepine, was initially assessed by Novartis Pharmaceuticals for treatment of acute mania rather than epilepsy. As of 2023, the results of three randomized controlled trials (on ClinicalTrials.gov) of licarbazepine in acute mania had not yet been published. In 2009, the European Medicines Agency approved eslicarbazepine acetate, a prodrug for the *S*-enantiomer of licarbazepine (Zebinix; BIAL-Portela), for the treatment of epilepsy. In 2013, the FDA approved eslicarbazepine acetate (Aptiom; submitted by Sunovion Pharmaceuticals under license from BIAL-Portela) for epilepsy. Although eslicarbazepine acetate may have greater tolerability than carbamazepine and does not carry black box warnings, its efficacy in acute mania has not been established (Grunze *et al.* 2015).

Structure-Activity Relationships

Carbamazepine is an iminostilbene derivative with a dibenzoazepine nucleus. It has a carbamyl (carboxamide) group at position 5 that seems to be associated with substantial anticonvulsant effects. Like imipramine, carbamazepine has a tricyclic structure. However, imipramine has a 5-aryl substituent, whereas carbamazepine has a 5-carboxamide substituent; this structural difference is thought to mediate carbamazepine's markedly different effects in comparison with imipramine, as described later in this chapter (see section "Mechanisms of Action"). Oxcarbazepine differs structurally from carbamazepine only in that it has a ketone substitution at the 10,11-position, and (as noted later) the bulk of the evidence thus far suggests that this structural similarity is paralleled by mechanistic similarity. Eslicarbazepine acetate, like oxcarbazepine, has a stabilizing subgroup at the 10,11-position (an acetoxy side chain) and is metabolized to the *S*-isomer of the common metabolite of oxcarbazepine, licarbazepine (Almeida and Soares-da-Silva 2007).

Pharmacological Profiles

Carbamazepine and oxcarbazepine have preclinical anticonvulsant profiles that are somewhat similar to that of phenytoin and less broad than that of valproate or lamotrigine. Like phenytoin, valproate, and lamotrigine, carbamazepine and oxcarbazepine are effective in the maximal electroshock model of generalized tonic and/or clonic seizures and in seizure blockade resulting from amygdala kindling (a model of partial seizures). Like phenytoin but unlike valproate and lamotrigine, carbamazepine and oxcarbazepine are not effective in the pentylenetetrazole model of absence seizures. In addition, like phenytoin and lamotrigine (but unlike valproate), carbamazepine and oxcarbazepine fail to block kindling development (a model of epileptogenesis).

As expected from their preclinical profiles, carbamazepine and oxcarbazepine--like phenytoin, valproate, and lamotrigine--are effective in partial seizures with and without secondary generalization. And like phenytoin but unlike valproate and lamotrigine, carbamazepine and oxcarbazepine are ineffective in absence seizures. Carbamazepine and oxcarbazepine also have analgesic effects in paroxysmal pain syndromes and thus are effective in trigeminal neuralgia.

Eslicarbazepine acetate, which shares a common active metabolite with oxcarbazepine, has a similar preclinical anticonvulsant profile. Thus, eslicarbazepine acetate, like oxcarbazepine, is effective in the maximal electroshock model of generalized tonic and/or clonic seizures and in blocking seizures resulting from amygdala kindling (Almeida and Soares-da-Silva 2007).

Pharmacokinetics and Disposition

Carbamazepine

Carbamazepine is available in the United States as a proprietary product (Tegretol; Novartis Pharmaceuticals 2015) supplied in suspension (100 mg/5 mL), chewable tablet (100 mg), immediate-release tablet (200 mg), and extended-release tablet (Tegretol XR 100, 200, and 400 mg) formulations. The additional proprietary formulation Carbatrol, an extended-release capsule, is marketed for epilepsy and is available in strengths of 100, 200, and 300 mg (Shire US 2013). The FDA has approved generic equivalent products for all of these dosage forms. Equetro (Validus Pharmaceuticals 2021), another extended-release capsule, is available in the same strengths as Carbatrol and is FDA approved and marketed for bipolar disorder (U.S.

Food and Drug Administration 2023). Intramuscular and depot formulations are not available.

Carbamazepine is extensively metabolized, with only about 3% being excreted unchanged in the urine. The main metabolic pathway of carbamazepine (to its active 10,11-epoxide, carbamazepine-E) seems to be primarily via cytochrome P450 (CYP) isozyme CYP3A3/4 (Figure 39-1, top), with a minor contribution by CYP2C8 (Kerr *et al.* 1994). This epoxide pathway accounts for about 40% of carbamazepine disposition, and this percentage is even greater in patients with induced epoxide pathway metabolism (Faigle and Feldmann 1995). The frequency distribution of carbamazepine's kinetic parameters is unimodal, consistent with CYP3A3/4 being the crucial isoform. With enzyme induction of the epoxide pathway (presumably via CYP3A3/4 induction), formation of carbamazepine-E triples, causing the carbamazepine-E/carbamazepine ratio to increase (Eichelbaum *et al.* 1985). Other metabolic pathways include aromatic hydroxylation (25%), which is apparently via CYP1A2, and glucuronide conjugation of the carbamoyl side chain (15%) (Staines *et al.* 2004) to yield inactive metabolites.

Carbamazepine has erratic absorption and a bioavailability of approximately 80%. Tablets should not be stored above 30degC (86degF) and should be protected from light and moisture (Nightingale 1990; Novartis Pharmaceuticals 2015). Carbamazepine is about 75% bound to plasma proteins and has a moderate volume of distribution of approximately 1 L/kg. Before autoinduction of the epoxide pathway, the half-life of carbamazepine is about 24 hours and clearance is about 25 mL/minute.

After autoinduction (2-4 weeks into therapy), the half-life of carbamazepine decreases to approximately 8 hours and clearance increases to about 75 mL/minute. These changes may require dosage adjustment to maintain adequate blood concentrations and therapeutic effects. The active carbamazepine-E metabolite has a half-life of approximately 6 hours and is converted to an inactive diol (carbamazepineD) by epoxide hydrolase. The extended-release carbamazepine formulations given twice

daily yield steady-state carbamazepinetarget, with carbamazepine serum concentrations similar to those seen with the immediate-release formulation given four times daily (Garnett *et al.* 1998; Thakker *et al.* 1992), although clinical data support the use of once-nightly dosing for patients with mood disorders for help with sleep and daytime side effects.

When carbamazepine is used in the treatment of acute mania, two divergent clinical needs influence the rate of dosage titration. The need for rapid control of the manic syndrome should be balanced against the need to minimize adverse effects, which can be worsened with overly aggressive escalation of the carbamazepine dosage. Thus, although a loading-dose strategy may be tolerated and effective with valproate in the treatment of mania (Keck *et al.* 1993), the potential for neurotoxic adverse effects (e.g., CNS symptoms such as dizziness, somnolence, cognitive slowness, tremors, ataxia, and slurred speech) limits the use of such an aggressive approach with carbamazepine.

In inpatient treatment of mania, carbamazepine is commonly started at 400-800 mg/day in divided doses and increased as tolerated (by 200 mg/day every 1-4 days) to provide clinical efficacy. In controlled studies, the beaded extended-release capsule formulation was started at 200 mg bid and increased daily by 200 mg to a final dosage as high as 1,600 mg/day (Weisler *et al.* 2004, 2005). Managing dosage titration against adverse effects is more important than targeting a specific blood concentration range. The usual dosage range is 800-1,600 mg/day given in up to three or four divided doses with the immediate-release formulation. Extended-release formulations permit two divided doses per day and may even allow most or all of the daily dosage to be taken at bedtime for patients with mood disorder. Carbamazepine has a fairly rapid onset of antimanic efficacy. Thus, if clinical improvement has not occurred after 7-10 days, the clinician should consider augmentation or alternative strategies.

In a 6-month open-label extension of controlled studies in acute mania, carbamazepine beaded extended-release capsules were started at 200 mg bid and increased by 200 mg every 3 days (vs. every day in the acute studies) to a final dosage as high as 1,600 mg/day (Ketter *et al.* 2004). This approach decreased the incidence of CNS (dizziness, somnolence, ataxia), digestive system (nausea, vomiting), and dermatological (pruritus) adverse effects by approximately 50%.

In less acute situations such as depression or prophylaxis, carbamazepine is often started at 100-200 mg/night and is increased as necessary and tolerated by 200 mg every 4-7 days. Even more gradual initiation strategies may be necessary to alleviate adverse effects. Thus, starting with 50 mg (half of a chewable 100-mg tablet) at bedtime and increasing the daily dosage by 50 mg every few days can result in a better-tolerated initiation. Often, given dosages of carbamazepine may be better tolerated after 1 month of therapy, once autoinduction of carbamazepine metabolism has decreased the serum carbamazepine concentrations (Cereghino 1975) and accommodation and tolerance to adverse effects such as sedation have occurred. In two carbamazepine-versus-lithium maintenance studies, trough serum carbamazepine concentrations were maintained at 4-12 mg/mL, with a mean of 6.4 mg/mL (Greil *et al.* 1997) and 7.7 mg/mL (Denicoff *et al.* 1997).

Because carbamazepine dosages and serum and cerebrospinal fluid concentrations do not correlate with the drug's psychotropic efficacy (Post 1989; Post *et al.* 1983, 1984a), clinical management involves gradual upward titration until adequate therapeutic efficacy is achieved or adverse effects supervene. The 4-to 12-mg/mL serum carbamazepine concentration range used in epilepsy may be considered as a broad

target, with carbamazepine serum concentrations used as checks for pharmacokinetic problems, but frequent blood level monitoring is not required. The active carbamazepine-E metabolite can yield therapeutic and adverse effects similar to those of carbamazepine, but it is not detected in conventional carbamazepine assays.

In responders, a dose-response relationship may be evident, so slowly increasing carbamazepine dosages to maximize response in the absence of significant adverse effects would be an appropriate clinical strategy. However, if there is no hint of therapeutic response at moderate dosages, it is unlikely that increasing to very high dosages would be beneficial.

Oxcarbazepine

Oxcarbazepine is available in the United States as a proprietary product (Trileptal; Novartis Pharmaceuticals 2017) supplied in suspension (300 mg/5 mL) and tablet (150, 300, and 600 mg) formulations. FDA-approved generic products are available for both of these dosage forms. A novel once-daily extended-release formulation (Oxtellar XR; Supernus Pharmaceuticals 2018) has also been approved for the adjunctive treatment of partial seizures in adults and in children ages 6-17 years. Limited data suggest that this formulation has enhanced tolerability (Chung *et al.* 2016). Intramuscular and depot formulations of oxcarbazepine are not available.

Oxcarbazepine is 96% absorbed, and the modest effect of food on oxcarbazepine kinetics does not seem to be of therapeutic consequence (Degen *et al.* 1994). Oxcarbazepine is 60% bound to plasma proteins. Like carbamazepine, oxcarbazepine has a complex metabolism (Figure 39-1, bottom). Thus, oxcarbazepine is rapidly reduced to an active monohydroxy derivative (MHD) by cytosol arylketone reductase. The MHD form (also called licarbazepine) is 40% bound to plasma proteins, has a moderate volume of distribution of about 0.8 L/kg, and has a half-life of approximately 9 hours. Oxcarbazepine is eliminated primarily in the form of MHD (70%) and MHD glucuronide conjugates (20%), with a small proportion (10%) eliminated in the form of oxcarbazepine glucuronide conjugates and carbamazepineD.

Oxcarbazepine does not trigger autoinduction, and it causes substantially less heteroinduction than does carbamazepine. As described later in this chapter (see section "Drug-Drug Interactions"), medication interactions are thus less problematic with oxcarbazepine than with carbamazepine (Baruzzi *et al.* 1994).

Oxcarbazepine is started at 150 mg/day and increased every other day by 150 mg to a target of 1,200-1,600 mg/day in two to three divided doses. Further dosage increases up to 2,400 mg/day may be clinically indicated. In small trials of oxcarbazepine in acute mania, mean oxcarbazepine dosages were 1,400-2,400 mg/day (Emrich 1990; Emrich *et al.* 1983). As with carbamazepine, oxcarbazepine is titrated to the desired clinical effect as tolerated when used to treat patients with bipolar disorder, with the serum concentration range used in epilepsy considered a broad target and with oxcarbazepine serum concentrations used as checks for pharmacokinetic problems. Equipotent doses of oxcarbazepine range from 1.2 to 1.5 times the carbamazepine dose. For Oxtellar XR, all-HS (bedtime) dosing is not unreasonable.

Eslicarbazepine Acetate

Eslicarbazepine acetate is available in the United States as a proprietary product (Aptiom; Sunovion Pharmaceuticals 2013) supplied in tablet strengths of 200, 400, 600, and 800 mg. FDA-approved generic equivalent products are available. Extended-release, intramuscular, and depot formulations of eslicarbazepine acetate are not available.

Licarbazepine is the active MHD product of oxcarbazepine, and eslicarbazepine is the *S*-isomer of licarbazepine (Figure 39-2). Eslicarbazepine acetate is a prodrug of *S*-licarbazepine. Licarbazepine is 40% bound to plasma proteins, has a moderate volume of distribution (about 0.8 L/kg), and has a half-life of about 20-24 hours (Zaccara *et al.* 2015). Elimination is mainly through the kidneys, unchanged or glucuronidated (Zaccara *et al.* 2015). Eslicarbazepine acetate pharmacokinetics do not seem to be affected in patients with moderate hepatic impairment (Almeida *et al.* 2008).

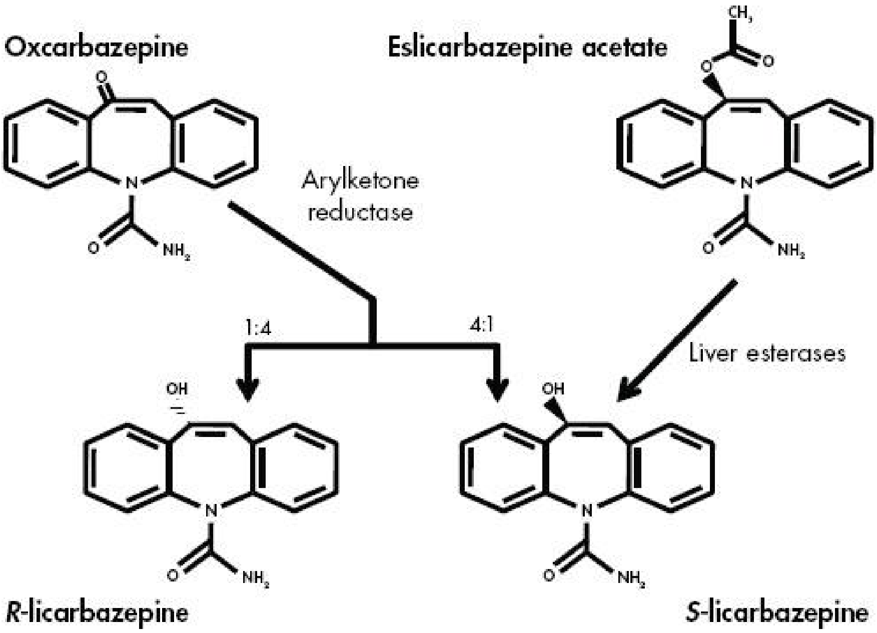

FIGURE 39-2. Oxcarbazepine and eslicarbazepine acetate metabolism.

Oxcarbazepine is metabolized to the active monohydroxy derivative as a racemic mixture with a higher (4:1) ratio of the *S*-enantiomer compared with the *R*-enantiomer. Eslicarbazepine acetate is rapidly metabolized to the common but specifically *S*-enantiomer of the monohydroxy derivative (Bialer 2006).

In a 2015 study evaluating the safety of two dosage-titration regimens of eslicarbazepine acetate in the treatment of patients with bipolar I disorder and acute mania, eslicarbazepine acetate was started at 600 or 800 mg/day and increased every 3 days by 600 or 800 mg to a target dosage of 1,800 or 2,400 mg/day, respectively. Despite the aggressive titration schedule, adverse effects were of mostly mild to moderate intensity but response did not exceed that of placebo (Grunze *et al.* 2015).

Transitioning a patient from oxcarbazepine to eslicarbazepine acetate would be expected to be relatively straightforward, with an oxcarbazepine/eslicarbazepine acetate dose ratio of 1:1, and could occur within 1 day. By contrast, transitioning a patient from carbamazepine to eslicarbazepine acetate would be considerably more complicated, with a carbamazepine/eslicarbazepine acetate dose ratio of 1:1.3, and would require at least 1-2 weeks, as clinically determined (Peltola *et al.* 2015).

Mechanisms of Action

Carbamazepine and oxcarbazepine have both structural and mechanistic similarities. However, these agents have such a diversity of biochemical effects that linking these mechanisms to their varying clinical actions presents a considerable challenge.

Carbamazepine

Although carbamazepine has a tricyclic structure like that of imipramine, the two agents have markedly different neurochemical, hepatic, and clinical effects. Carbamazepine lacks imipramine's major effects on monoamine reuptake and high affinity for histaminergic, cholinergic, adrenergic b, and dopamine receptors. However, carbamazepine has a wide range of other cellular and intracellular effects.

One useful way of considering carbamazepine's diverse mechanisms is from the perspective of onset of action (Post 1988). Carbamazepine's cellular actions with acute onset that might parallel the time course of clinical anticonvulsant effects include decreasing sodium influx and glutamate release, increasing potassium conductance, and interacting with peripheral benzodiazepine and a_2-adrenergic receptors. Acute or subchronic actions--such as increasing striatal cholinergic neurotransmission; decreasing adenylate cyclase activity stimulated by dopamine, norepinephrine, and serotonin; and decreasing turnover of dopamine, norepinephrine, and GABA--may be pertinent to carbamazepine's clinical antimanic effects. Finally, the actions requiring chronic administration--including increasing serum and urinary free cortisol, free tryptophan, substance P sensitivity, and adenosine A1 receptors and paradoxically decreasing cerebrospinal somatostatin--may be those that are most closely related to carbamazepine's clinical antidepressant effects.

Oxcarbazepine

Compared with the knowledge base on carbamazepine's mechanisms of action, less is known about oxcarbazepine (and thus eslicarbazepine acetate, given their common active molecules). Most evidence thus far suggests that oxcarbazepine's structural similarity to carbamazepine is paralleled by mechanistic similarity (Ambrosio *et al.*

2002). For example, oxcarbazepine, like carbamazepine, appears to decrease sodium (Benes *et al.* 1999; Wamil *et al.* 1994) and calcium (Stefani *et al.* 1995) influx, glutamate release (Ambrosio *et al.* 2001), and serum thyroxine concentrations (Isojarvi *et al.* 2001b); to increase potassium conductance (McLean *et al.* 1994) and dopaminergic (Joca *et al.* 2000) neurotransmission; and to block adenosine A_1 receptors (Deckert *et al.* 1993). However, there may be some mechanistic dissimilarities, particularly given the marked difference between oxcarbazepine and carbamazepine in the degree of hepatic enzyme induction. For example, oxcarbazepine seems to be a less potent modulator of voltage-gated calcium channels than is carbamazepine (Schmutz *et al.* 1994; Stefani *et al.* 1997). The general oxcarbazepine-carbamazepine mechanistic overlap is consistent with the hypothesis that these medications have generally similar

effects in bipolar disorder, which in turn is consistent with preliminary clinical observations; however, these similarities remain to be established in large controlled clinical studies.

Eslicarbazepine Acetate

Eslicarbazepine acetate and oxcarbazepine likely have a similar mode of action because they share the same main active metabolite licarbazepine--although the oxcarbazepine metabolite is racemic licarbazepine, whereas the eslicarbazepine acetate metabolite is exclusively the S-isomer of licarbazepine (Almeida and Soares-da-Silva 2007; Schutz *et al.* 1986). Thus, eslicarbazepine acetate behaves as a blocker of the voltage-gated sodium channel (Almeida and Soares-da-Silva 2007). Whereas eslicarbazepine acetate reduces voltage-gated sodium channel availability through enhancement of slow inactivation, carbamazepine acts by altering fast inactivation of the channel (Hebeisen *et al.* 2015). Eslicarbazepine and carbamazepine also differ with regard to submaximal GABA currents, Kv7.2 potassium channel outward currents, and high-and low-affinity Cav3.2 calcium channel inward currents (Keating 2014). Oxcarbazepine and eslicarbazepine acetate may have some mechanistic differences as well, with carbamazepine and oxcarbazepine enhancing excitatory synaptic transmission via antagonism of the adenosine A_1 receptor at therapeutic doses; eslicarbazepine acetate does so only at supratherapeutic high doses (Booker *et al.* 2015).

Indications and Efficacy

Seizure Disorders and Trigeminal Neuralgia

In the United States, carbamazepine (as immediate-release tablets, suspension, and Carbatrol extended-release capsules) is approved as monotherapy for the treatment of trigeminal neuralgia and complex partial, generalized tonic-clonic, and mixed seizure disorders (U.S. Food and Drug Administration 2023). Oxcarbazepine is approved for the treatment of partial seizures as monotherapy in adults and as adjunctive therapy in adults and children older than 4 years (U.S. Food and Drug Administration 2023). Eslicarbazepine is approved as monotherapy or adjunctive treatment for partial-onset seizures (U.S. Food and Drug Administration 2023).

Carbamazepine and oxcarbazepine seem to have overlapping anticonvulsant effects, with similar efficacy in patients with newly diagnosed epilepsy (Dam *et al.* 1989). However, there may be dissimilarities. For example, switching to oxcarbazepine may be effective for patients for whom carbamazepine results in an inadequate response or intolerable adverse effects (Beydoun *et al.* 2000; Van Parys and Meinardi 1994); adding oxcarbazepine may improve efficacy for patients whose symptoms respond inadequately to carbamazepine (Barcs *et al.* 2000; Glauser *et al.* 2000).

Acute Mania

The FDA approved a proprietary carbamazepine beaded extended-release capsule formulation (Equetro) for the treatment of acute manic and mixed episodes in patients with bipolar disorder in late 2004. Twenty-six controlled studies have investigated the efficacy of carbamazepine, oxcarbazepine, and eslicarbazepine acetate in acute mania (summarized in Table 39-1). In these studies, there is more compelling evidence for the efficacy of carbamazepine (18 studies encompassing 594 patients receiving carbamazepine) compared with that for oxcarbazepine (5 studies including 119 patients receiving oxcarbazepine) and ambiguous results with eslicarbazepine acetate (2 studies encompassing 146 patients receiving eslicarbazepine acetate).

Carbamazepine and Oxcarbazepine

Two trials reporting that a proprietary carbamazepine beaded extended-release capsule formulation (Equetro) was superior to placebo are of particular interest, because they used a randomized double-blind, placebo-controlled design (Weisler *et al.* 2004, 2005) and led to the FDA indication for the treatment of acute manic and mixed episodes in patients with bipolar disorder. These reports are consistent with multiple earlier studies using placebo-drug-placebo, active comparator (lithium or first-generation antipsychotics), and adjunctive designs.

Thus, across studies using diverse paradigms (see Table 39-1), overall antimanic response rates with carbamazepine were generally comparable to those seen with lithium or first-generation antipsychotics or in other studies with valproate (Ketter 2010). Taken together, this collection of clinical trials provides substantial evidence for the acute antimanic efficacy of carbamazepine and some preliminary evidence for the acute antimanic efficacy of oxcarbazepine. Interestingly, the body of existing data for carbamazepine seems to be greater than that initially used by the FDA to approve lithium for the treatment of acute mania.

For carbamazepine, improvement appears to occur across the entire manic syndrome and does not seem to be attributable to nonspecific sedative properties because patients often show dramatic clinical improvement in the absence of marked sedation. Carbamazepine and oxcarbazepine are frequently used in combination with other medications in the acute treatment of mania, so knowledge of carbamazepine's extensive and oxcarbazepine's more limited drug-drug interactions (as described in the section "Drug-Drug Interactions") is often required to achieve optimal outcomes.

Eslicarbazepine Acetate

In two 3-week studies of eslicarbazepine acetate in acute mania, the drug did not separate from placebo on the primary outcome measure of Young Mania Rating Scale score change; however, Clinical Global Impression Scale score changes were suggestive of efficacy in one study (Grunze *et al.* 2015). High rates of placebo response and poor study recruitment (leading to premature study termination) may have contributed to treatment failure in the second study (Grunze *et al.* 2015).

Acute Depression

Limited controlled data exist regarding the acute antidepressant effects of carbamazepine (Table 39-2). To date, there are no published controlled studies examining the antidepressant effects of oxcarbazepine or eslicarbazepine acetate. However, in a study in which 10 patients with depression initially responded when carbamazepine was substituted for placebo, response was reconfirmed by relapse occurring when placebo was again given, and a subsequent re-response to blind retreatment with carbamazepine was observed (Ballenger and Post 1978). Although carbamazepine seems to have weaker antidepressant than antimanic properties, some evidence suggests that it may provide antidepressant benefit for about one-third of individuals with treatment-resistant depression (Neumann *et al.* 1984; Post *et al.* 1986; Small 1990). In a Chinese study, carbamazepine produced a response rate closer to two-thirds in patients with non-treatment-resistant depression (Zhang *et al.* 2007). Unfortunately, most of these studies are limited by their use of small samples of heterogeneous patients with highly treatment-resistant depression (both bipolar and unipolar).

TABLE 39-2. Carbamazepine (CBZ) in acute depression: four controlled studies

Maintenance and Relapse-Prevention Treatment

Carbamazepine and Oxcarbazepine

A series of 18 double-blind randomized, open randomized, or otherwise partially controlled studies examined the efficacy of carbamazepine and oxcarbazepine in maintenance treatment of bipolar disorder (summarized in Table 39-3). The 15 carbamazepine trials are consistent with a very substantial open literature suggesting that this drug is effective in preventing mood episodes when administered during long-term treatment either alone or in combination with lithium in previous lithium nonresponders (see Table 39-3). Indeed, five reviews of different subsets of studies included in Table 39-3 broadly indicated that carbamazepine and lithium monotherapy had comparable prophylactic effects in patients with bipolar disorder (Ceron-Litvoc *et al.* 2009; Dardennes *et al.* 1995; Davis *et al.* 1999; Hirschfeld and Kasper 2004; Smith *et al.* 2007). One study comparing carbamazepine with oxcarbazepine randomly assigned 153 patients with symptoms that responded inadequately to lithium, and the investigators reported that oxcarbazepine was superior to carbamazepine on all measures at weeks 4 and 8 (Juruena *et al.* 2009).

[a] Weighted means of patients with response data.

Carbamazepine may have equal *prophylactic* antidepressant and antimanic efficacy compared with its less potent *acute* antidepressant vs antimanic effects. In contrast, data regarding the efficacy of oxcarbazepine in preventing new mood episodes in patients with bipolar disorder are more limited (Cabrera *et al.* 1986; Vieta *et al.* 2008; Wildgrube 1990). A 2008 Cochrane Review assessed the available data as inadequate to recommend oxcarbazepine in the maintenance treatment of bipolar disorder (Vasudev *et al.* 2008).

1041

1042

In one study, the overall analysis suggested that maintenance treatment was more effective with lithium than with carbamazepine (Greil *et al.* 1997). However, subgroup differences may exist. For example, lithium may be more effective for patients with "classical" bipolar disorder (e.g., bipolar I disorder with no mood-incongruent delusions, psychotic features, or comorbidity), whereas carbamazepine may be more effective for patients with "nonclassical" bipolar disorder (e.g., bipolar II disorder, DSM-IV [American Psychiatric Association 1994] bipolar disorder not otherwise specified, bipolar disorder with mood-incongruent delusions, and anxiety or substance abuse comorbidity) (Greil *et al.* 1998).

In another study, lithium maintenance treatment appeared to be more effective than carbamazepine for patients with no more than 6 months of prior exposure to either agent (Hartong *et al.* 2003). However, this advantage was offset by more early discontinuations in the lithium group, so that similar proportions (about one-third) of patients in both groups completed 2 years with no episode. Patients taking lithium versus carbamazepine tended to have a somewhat greater risk of episodes in the first 3 months and markedly less risk of episodes after the first 3 months, with a recurrence risk of only 10% per year with lithium after the first 3 months. Patients taking carbamazepine had a more consistent rate of relapse or recurrence of approximately 40% per year.

Some carbamazepine relapse-prevention trials have been criticized for their methodological limitations (Murphy *et al.* 1989), although such difficulties are common in maintenance studies. (For example, divalproex and lithium failed to separate from placebo on the primary efficacy measure in a 1-year maintenance study [Bowden *et al.* 2000], a result at least partially attributable to methodological problems.) Taken together, this collection of randomized placebo-controlled, placebo-drug-placebo, and lithium comparator studies and trials in rapid-cycling and lithium-resistant populations provides substantial evidence for the preventive efficacy of carbamazepine (Prien and Gelenberg 1989). Carbamazepine may be effective for some individuals with valproate-resistant illness (Post *et al.* 1984b), and the carbamazepine-valproate combination may be effective for patients who experience little or no response to either agent alone (Keck *et al.* 1992; Ketter *et al.* 1992).

In a retrospective study, 22 of 34 patients (65%) had treatment-resistant bipolar disorder that responded to primarily adjunctive open carbamazepine acutely. However, only 9 of the 22 (41%) were considered probable or clear responders when assessed 3-4 years later (Frankenburg *et al.* 1988). Post and colleagues suggested that the loss of carbamazepine prophylactic efficacy over time may be related to a unique form of contingent tolerance (Post and Weiss 2011; Post *et al.* 1990). In these instances, techniques such as switching to another treatment regimen with a different mechanism of action or returning later to carbamazepine (after a period of not taking it) are worth considering based on case reports and anecdotal observations.

Eslicarbazepine Acetate

A 6-month continuation study investigated the efficacy of three different dosages of eslicarbazepine acetate (300, 900, and 1,800 mg/day) in preventing symptom recurrence in patients with bipolar disorder who had participated in the earlier placebo-controlled studies of eslicarbazepine acetate in acute mania. Of the 85 patients who experienced a symptom response during acute treatment and were randomly assigned to one of three dosage groups, at least 50% did not show any clinical worsening; however, there was no significant difference between dosage groups (Grunze *et al.* 2015).

Response Predictors

Predictors of carbamazepine response have only been preliminarily elucidated. Carbamazepine can be effective for patients with a history of lithium unresponsiveness or intolerance (Okuma *et al.* 1979; Post *et al.* 1987). Nonclassical bipolar disorder (Greil *et al.* 1998; Small *et al.* 1991) and stable or decreasing episode frequency (Post *et al.* 1990) may be associated with carbamazepine response. Patients with a history of affective illness in first-degree relatives may experience a preferential response to lithium, whereas the converse may be the case for carbamazepine (Ballenger and Post 1978; Post *et al.* 1987). Patients with comorbid neurological or substance abuse problems and illness that responds inadequately to lithium may experience a response to carbamazepine or valproate (Himmelhoch 1987; Himmelhoch and Garfinkel 1986). Preliminary observations indicate that baseline cerebral (left insula) hypermetabolism may be a marker of carbamazepine antidepressant response, in contrast with left insula hypometabolism for nimodipine response (Ketter *et al.* 1999). Reports vary with respect to the relationship between carbamazepine response and dysphoric manic presentations (Lusznat *et al.* 1988; Post *et al.* 1989) or illness severity (Post *et al.*

1987; Small *et al.* 1991). Antidepressant responses to carbamazepine may be seen in patients with more severe depression, more discrete depressive episodes, less chronicity, and greater decreases in serum thyroxine concentrations with carbamazepine (Post *et al.* 1986, 1991).

Although the initial studies of Post *et al.* and Okuma *et al.* indicated that rapid-cycling illness was responsive to carbamazepine for some patients (Okuma 1983; Okuma *et al.* 1981; Post *et al.* 1987), other investigators found less robust results (Dilsaver *et al.* 1993; Joyce 1988). As with lithium, later studies by Okuma *et al.* reported a lower carbamazepine maintenance response rate in rapid-cycling compared with non-rapid-cycling illness (Okuma 1993). However, even these patients with rapid cycling had a higher carbamazepine response rate (40%) than those reported with other agents in other studies. Denicoff *et al.* (1997) also observed that patients with a history of rapid cycling had a lower response rate to maintenance carbamazepine compared with those without such a history (19% vs. 54%), but rapid cyclers did well with the combination of lithium and carbamazepine.

Side Effects and Toxicology

Baseline evaluation of patients with bipolar disorder includes not only psychosocial assessment but also a general medical evaluation. Assessment commonly includes the following: history, physical examination, complete blood count with differential and platelets, electrolytes, toxicology, and tests for pregnancy and renal, hepatic, and thyroid function as well as other chemistries and electrocardiograms as clinically indicated (American Psychiatric Association 2002). Such evaluation provides baseline values for parameters that influence decisions about the choice of medication and intensity of clinical and laboratory monitoring.

Carbamazepine

Adverse effects can impact the utility of carbamazepine in the treatment of bipolar disorder, but most can be managed with careful individualized dose titration. In a pooled analysis of two multicenter acute mania FDA registration studies of a proprietary extended-release capsule formulation of carbamazepine (Equetro), the number needed to harm for somnolence was 6 and the number for at least 7% weight gain was 23 (Ketter *et al.* 2011). This result suggests that neurocognitive adverse effects might limit carbamazepine utility more than weight gain (Ketter 2015). However, the sedative side effects were assessed when patients were dosed twice a day, and all-nighttime or mostly-nighttime dosing should markedly lessen this problem. Some patients may tolerate carbamazepine better than other agents, particularly during longer-term treatment, because it seems to have a low propensity to cause adverse effects, such as weight gain and metabolic disturbance, that can limit the utility of some other agents (Akiskal *et al.* 2005; Ketter 2015).

Carbamazepine has several common dose-related adverse effects that generally can be minimized by attention to drug-drug interactions and gradual dose titration or reversed by decreasing dosage. At high doses, patients can develop neurotoxicity with sedation, ataxia, diplopia, and nystagmus, particularly early in therapy with acute-release formulations, before the autoinduction process is complete and tolerance to the CNS adverse effects of carbamazepine develops. Because there is wide interindividual variation in susceptibility to adverse effects at any given concentration, it is most useful clinically to titrate doses against each patient's adverse effects rather than targeting a fixed dosage or serum concentration range.

Neurotoxic effects that emerge 1-2 hours after an individual dose often signal that the adverse-effect threshold has been exceeded and that dose redistribution (i.e., spreading out the doses or giving more of the dose at bedtime) or dosage reduction may be required. Use of extended-release formulations may attenuate carbamazepine peak serum concentrations, enhancing tolerability.

Carbamazepine commonly causes benign hematological (leukopenia, thrombocytopenia), dermatological (rash), electrolyte (asymptomatic hyponatremia), and hepatic (transaminase elevations) problems. Analogous serious problems are much less common. For example, mild leukopenia and benign rash occur for up to 1 in 10 patients, with only a slight possibility that these usually benign phenomena are heralding malignant aplastic anemia and Stevens-Johnson syndrome, which is seen in about 1 in 100,000 patients (Kramlinger *et al.* 1994; Tohen *et al.* 1995). Bone loss from taking anticonvulsants, including carbamazepine, was significantly prevented for patients receiving risedronate versus placebo as add-ons to calcium and vitamin D (Lazzari *et al.* 2013).

In view of the risk of rare but serious decreases in blood counts, which warrant a black box warning in the carbamazepine prescribing information, it is important to alert patients to seek immediate medical evaluation if they develop signs and symptoms of possible hematological reactions such as fever, sore throat, oral ulcers, petechiae, and easy bruising or bleeding. Hematological monitoring must be intensified for patients with low or marginal leukocyte counts, and carbamazepine is generally discontinued if the leukocyte count falls below 3,000/mL or the granulocyte count is less than 1,000/mL. In the instance of benign leukopenia, the addition of lithium can

increase the neutrophil count back toward normal (Kramlinger and Post 1990), but this strategy is not likely to be helpful for the suppression of red cells or platelets, which likely indicates a more problematic process.

Serious rash may occur in about 1 in 10,000-100,000 patients. The risk of serious and sometimes fatal dermatological reactions, including toxic epidermal necrolysis and Stevens-Johnson syndrome, may be increased 10-fold in certain Asian populations and has been strongly linked to the human leukocyte antigen *HLA-B*1502* allele (Novartis Pharmaceuticals 2015). Thus, the U.S. prescribing information includes a black box warning that individuals of Asian ancestry should be genetically tested for *HLA-B*1502* and that carriers of this allele should not be treated with carbamazepine. In addition, a 12-fold increased risk of drug-induced hypersensitivity syndrome (also called drug rash with eosinophilia and systemic symptoms) has been linked to *HLA-A*3101* in white individuals of northern European descent (McCormack *et al.* 2011).

Given the risk of serious rash, patients should be alerted to seek medical attention immediately if a rash develops. In particular, rash in patients presenting with systemic illness or involvement of the eyes, mouth, or bladder (dysuria) constitutes a medical emergency: carbamazepine should be discontinued immediately, and the patient should be assessed emergently (Scaparrotta *et al.* 2011). For more benign presentations, carbamazepine is generally discontinued because there is little ability to predict which cases will progress to more severe, potentially life-threatening problems. However, in rare instances of resistance to other medications except carbamazepine, a repeat trial of carbamazepine with a course of prednisone has usually been well tolerated (Murphy *et al.* 1991; Vick 1983). A substantial number of patients with carbamazepine-induced rash may not develop a rash on re-exposure (even without prednisone coverage) but if a rash develops again, it usually appears more rapidly than the first occurrence. Only 25%-30% of patients who develop a rash with carbamazepine also develop a rash (cross-sensitivity) with oxcarbazepine.

Carbamazepine, in common with multiple other anticonvulsant medications (including oxcarbazepine and eslicarbazepine acetate), may increase the risk of suicidality, including suicidal behavior or ideation. Data from controlled trials of anticonvulsant medications compared with placebo showed a 1.5-fold increased risk from 0.57% to 0.85% for psychiatric patients (Novartis Pharmaceuticals 2015).

Because of the risk of rare hepatitis, patients should be advised to seek medical evaluation immediately if they develop malaise, abdominal pain, or other marked gastrointestinal symptoms. In general, carbamazepine (like other anticonvulsants) should be discontinued if liver function values exceed three times the upper limit of the normal range (Martinez *et al.* 1993).

Carbamazepine may affect cardiac conduction and should be used with caution in patients with cardiac disorders such as heart block. A baseline electrocardiogram is worth considering if the patient has a history of cardiac abnormalities or arrhythmias.

Conservative laboratory monitoring during carbamazepine therapy includes baseline studies and evaluation of complete blood count, differential, platelets, and hepatic indices at treatment initiation, then biweekly (at 2, 4, 6, and 8 weeks), and then every 3 months (American Psychiatric Association 1994, 2002); however, much less frequent monitoring is typically practiced in neurology and followed by psychiatrists. Most of the serious hematological reactions occur within the first 3 months of therapy (Tohen *et al.* 1995). In contemporary clinical practice, clinically indicated

monitoring (e.g., when a patient becomes ill with a fever) is emphasized over scheduled monitoring. Patients who have abnormal or marginal indices at any point merit careful scheduled and clinically indicated monitoring. The U.S. prescribing information for the carbamazepine beaded extended-release capsule formulation recommends the following: obtaining a baseline complete blood count including platelets, possibly reticulocytes, possibly serum iron, and hepatic function tests; closely monitoring patients with low or decreased white blood cell counts or platelets; and considering discontinuation of carbamazepine if evidence indicates bone marrow depression (Validus Pharmaceuticals 2021). Serum carbamazepine concentrations are typically assessed at steady state and then as indicated by inefficacy or adverse effects, although frequent blood level monitoring to inform efficacy is not needed. An important clinical note is that because of autoinduction, carbamazepine concentrations may decrease during the first 2-3 weeks after treatment initiation (Eichelbaum *et al.* 1975), thus potentially requiring readjustment of steady-state dosing.

Dividing or reducing dosages, rescheduling individual doses in relation to mealtimes, and changing formulations can attenuate carbamazepine-induced gastrointestinal disturbance. The carbamazepine oral suspension may have more proximal absorption and thus may exacerbate upper gastrointestinal adverse effects (nausea and vomiting) or attenuate lower gastrointestinal effects (diarrhea). The reverse holds for extended-release preparations.

Weight gain and obesity are important clinical concerns in the management of bipolar disorder. Medications and the hyperphagia, hypersomnia, and anergy commonly seen in bipolar depression can contribute to this important obstacle to optimal outcomes. Carbamazepine is less likely than lithium (Coxhead *et al.* 1992; Denicoff *et al.* 1997) or valproate (Mattson *et al.* 1992) to cause weight gain. In one study, carbamazepine caused weight gain in patients with depression (but not mania), which seemed to be related to the degree of depression relief (Joffe *et al.* 1986). Nevertheless, in view of its relatively benign effect on weight, carbamazepine may provide an important alternative to other mood stabilizers for patients who struggle with weight gain and obesity. It is also important to emphasize that response to anticonvulsants is not a class effect in mania, and some patients with mania that does not respond to valproate may obtain a response with carbamazepine (Post *et al.* 1984b, 2007).

Carbamazepine can induce hyponatremia, which may be well tolerated by some younger patients but can be problematic at high doses and for elderly individuals. If an elderly patient develops confusion, serum sodium should be assessed. In rare instances, water intoxication and seizures can occur. In some cases, hyponatremia can be effectively counteracted or prevented with the addition of lithium or the antibiotic demeclocycline (Ringel and Brick 1986).

Carbamazepine increases plasma high-density lipoprotein (O'Neill *et al.* 1982) and total cholesterol (Brown *et al.* 1992) concentrations. However, the high-density lipoprotein/total cholesterol ratio does not change (O'Neill *et al.* 1982). Thus, carbamazepine-induced increases in total cholesterol are not likely to be clinically problematic in relation to atherosclerosis (Brown *et al.* 1992).

Carbamazepine seems to reduce serum concentrations of both female and male sex hormones (Verrotti *et al.* 2011), and higher-dosage formulations of birth control pills are likely to be needed. In common with several other anticonvulsants, carbamazepine may adversely affect bone density (Verrotti *et al.* 2010).

Previous studies show that carbamazepine is teratogenic (former FDA Pregnancy Category D) and is associated with low birth weight, craniofacial deformities, digital hypoplasia, and spina bifida (in approximately 3% of births; Jones *et al.* 1989; Rosa 1991). Folate supplementation may attenuate the risk of spina bifida, and fetal ultrasound studies may allow early detection. In one study of children born to women with epilepsy, in utero exposure to carbamazepine or valproate, but not to lamotrigine, had a detrimental effect on child neurodevelopment, although carbamazepine seemed less likely than valproate to cause major developmental delays (Cummings *et al.* 2011).

Carbamazepine is present in breast milk at concentrations about half those in maternal blood but may not accumulate in fetal blood (Froescher *et al.* 1984; Kuhnz *et al.* 1983; Pynnonen *et al.* 1977; Shimoyama *et al.* 2000). Clinicians may prefer to avoid the minor risks of exposing infants to carbamazepine in breast milk (Frey *et al.* 2002), and some may discourage breastfeeding among women taking carbamazepine (Novartis Pharmaceuticals 2015).

Oxcarbazepine

As with carbamazepine, adverse effects may limit oxcarbazepine therapy. However, oxcarbazepine may have tolerability advantages compared with carbamazepine (Dam *et al.* 1989), perhaps related in part to the absence of the carbamazepine-E metabolite. Of note, oxcarbazepine lacks black box warnings regarding serious rash, blood dyscrasias, or tissue typing, although it still has the class warning regarding increased risk of suicidality. Compared with carbamazepine, oxcarbazepine seems to have a lower propensity to cause neurotoxicity and rash. Approximately 75% of patients who develop a rash with carbamazepine will tolerate oxcarbazepine. Oxcarbazepine does not appear to require hematological monitoring.

Oxcarbazepine, like carbamazepine, may cause transaminase elevations and gastrointestinal adverse effects, but there is less weight gain than with valproate (Rattya *et al.* 1999) and less impact on lipids than with carbamazepine (Isojarvi *et al.* 1994). Hyponatremia is the one side effect that occurs more commonly with oxcarbazepine (Friis *et al.* 1993) than with carbamazepine (Isojarvi *et al.* 2001a). Although hyponatremia is often asymptomatic (Reinstein *et al.* 2002), clinicians should provide regular monitoring of serum sodium levels for elderly patients taking high dosages of oxcarbazepine.

Compared with carbamazepine, oxcarbazepine has less impact on female hormone blood concentrations, likely because of its less marked hepatic enzyme induction. However, oxcarbazepine induction of female hormone metabolism may still decrease the efficacy of hormonal contraceptives, which should be countered with dose increases (Fattore *et al.* 1999; Kramer *et al.* 1992). Oxcarbazepine, in common with carbamazepine and several other anticonvulsants, may adversely affect bone density (Verrotti *et al.* 2010).

To date, oxcarbazepine, in contrast with carbamazepine, has not been associated with congenital malformations in humans (former FDA Pregnancy Category C). Whether this is because of fewer oxcarbazepine exposures or the absence of the carbamazepine-E metabolite (rendering oxcarbazepine less teratogenic) is unknown. Oxcarbazepine is present in breast milk; therefore, as with carbamazepine, clinicians may prefer to avoid the risk of exposing infants to oxcarbazepine in breast milk and

may wish to discourage breastfeeding in women taking oxcarbazepine (Novartis Pharmaceuticals 2017)).

Eslicarbazepine Acetate

Adverse effects may limit oxcarbazepine therapy as with carbamazepine, but structural advantages may result in better tolerability with eslicarbazepine acetate (Almeida and Soares-da-Silva 2007). The most commonly reported adverse effects from two epilepsy registration studies included somnolence, dizziness, vertigo, ataxia, abnormal coordination, diplopia, fatigue, and headache (Sunovion Pharmaceuticals 2013). The risk of rash was low (about 1%). The risk of hyponatremia with eslicarbazepine acetate is unknown, with rates ranging from 0.6% to 1.3% in premarketing trials (Zaccara *et al.* 2015) and rates as high as 3% in postmarketing studies (Massot *et al.*

2014). Significant decreases in sodium levels ([?] 10 mEq/L) were more common with eslicarbazepine acetate than with placebo (Sunovion Pharmaceuticals 2013). Eslicarbazepine acetate may increase the QT interval on electrocardiograms (Vaz-Da-Silva *et al.* 2012).

Importantly, eslicarbazepine acetate, similar to oxcarbazepine, lacks black box warnings for serious rash, blood dyscrasias, or tissue typing. However, eslicarbazepine acetate still has the (non-black box) class warning regarding increased risk of suicidality.

To date, eslicarbazepine acetate, like oxcarbazepine, has not been associated with congenital malformations in humans (former FDA Pregnancy Category C). Eslicarbazepine acetate is excreted in breast milk (Sunovion Pharmaceuticals 2013).

Drug-Drug Interactions

Combination therapy is common in bipolar disorder, with up to two-thirds of patients taking more than one medication concurrently (Kupfer *et al.* 2002). Patients with treatment-resistant illness may require a stepped-care approach (Figure 39-3), and they seem to be receiving increasingly complex medication regimens (Frye *et al.* 2000). Carbamazepine, and to a lesser extent oxcarbazepine, has clinically significant drug-drug interactions that increase the complexity of managing bipolar disorder.

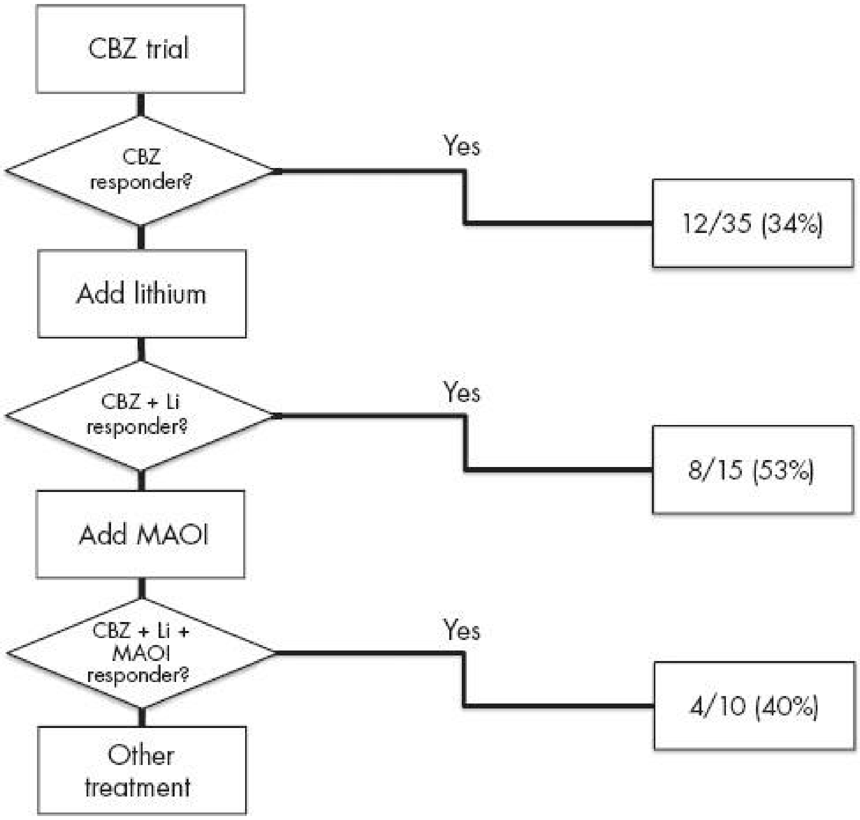

FIGURE 39-3. Stepped-care approach to bipolar depression.

Composite schema of results from three different studies in which patients with bipolar depression received carbamazepine (CBZ) monotherapy (Post *et al.* 1986), lithium (Li) added to carbamazepine (Kramlinger and Post 1989b), or a monoamine oxidase inhibitor (MAOI) added to carbamazepine with or without lithium (Ketter *et al.* 1995b). Each successive intervention resulted in additional efficacy.

Carbamazepine

The pharmacokinetic properties of carbamazepine are typical of older enzyme-inducing anticonvulsants but are atypical among medications prescribed by psychiatrists. Carbamazepine necessitates special care when used to treat patients who are concurrently taking other medications (Ketter *et al.* 1991a, 1991b). Three major principles appear to make important contributions to carbamazepine drug-drug interactions:

1. **Carbamazepine is a robust inducer of catabolic enzymes (including CYP3A3/4) and decreases the serum concentrations of many medications, including carbamazepine itself** (Table 39-4). Carbamazepine induces not only CYP3A3/4 and conjugates but also presumably other uncharacterized CYP isoforms. Thus, carbamazepine decreases serum concentrations of carbamazepine

itself (autoinduction) (Eichelbaum *et al.* 1975) and of other medications (heteroinduction); for example, it may cause major reductions in serum levels of methylphenidate (Behar *et al.* 1998). If carbamazepine is taken concurrently with certain medications, carbamazepine-induced decreases in serum concentrations can render these medications less effective (Table 39-4). Moreover, if carbamazepine is discontinued, serum concentrations of these other medications can increase, potentially leading to adverse effects.

2. **Carbamazepine metabolism (primarily CYP3A3/4) can be inhibited by certain enzyme inhibitors, yielding increases in serum carbamazepine concentrations and carbamazepine intoxication** (Table 39-5 and Figure 39-1, top). Autoinduction makes carbamazepine particularly vulnerable to the effects of enzyme inhibitors. Thus, a variety of agents that inhibit CYP3A3/4 can yield increased serum carbamazepine concentrations and side effects (Table 39-5 and Figure 39-1, top). Particularly noteworthy are the calcium channel blockers diltiazem and verapamil (but not nimodipine or nifedipine) and all of the erythromycin-like antibiotics.

3. **Carbamazepine has an active epoxide (carbamazepine-E) metabolite** (Figure 39-1, top). Valproate inhibits epoxide hydrolase, yielding increased serum carbamazepine-E (but not carbamazepine) concentrations (Table 39-5). Free carbamazepine may also increase because of valproate-induced displacement of carbamazepine protein binding.

TABLE 39-4. Selected drugs whose serum concentrations are DECREASED by carbamazepine (and oxcarbazepine)

Antidepressants	Anticonvulsants	Dihydropyridine CCBs
Bupropion	Carbamazepine	*Felodipine*
Citalopram	Ethosuximide	Nimodipine
Mirtazapine	Felbamate	

Note. Italic type indicates that serum concentrations of the medication may decrease to a clinically significant extent not only with carbamazepine but also with oxcarbazepine, hindering the efficacy of the agent. (?) = unclear clinical significance; CCBs = calcium channel blockers.

Sertraline
Tricyclics

Antipsychotics
Aripiprazole
Brexpiprazole
Cariprazine
Chlorpromazine (?)
Clozapine
Fluphenazine (?)
Haloperidol
Lumateperone
Olanzapine
Quetiapine (?)
Risperidone
Thiothixene (?)
Ziprasidone (?)

Anxiolytics/sedatives
Alprazolam (?)
Buspirone
Clonazepam
Eszopiclone (?)
Midazolam

d-Propoxyphene
Ritonavir
Ticlopidine (?)
Valproate (increases CBZ-E)

Note. (?) = unclear clinical significance; CBZ-E = carbamazepine-10,11-epoxide.

Carbamazepine has a wide variety of pharmacokinetic drug-drug interactions, in excess of and different from those seen with lithium or valproate. In the following subsections, we review carbamazepine drug interactions with other medications, with agents of particular interest in the management of mood disorders indicated in **boldface** type. The reader interested in detailed reviews of carbamazepine drug-drug interactions is referred to the review by Ketter *et al.* (1991a, 1991b).

Interactions With Mood Stabilizers and Anticonvulsants

The combination of carbamazepine and lithium is frequently used in bipolar disorder, and it may provide additive or synergistic antimanic (Kramlinger and Post 1989a) and antidepressant (Kramlinger and Post 1989b) effects. This combination is generally well tolerated, with merely additive (as opposed to synergistic or antagonistic) neurotoxicity (McGinness *et al.* 1990), which can be minimized by gradual dosage escalation. Pharmacokinetic interactions between these drugs do not occur because lithium has no hepatic metabolism. Adverse effects of lithium and carbamazepine can be either additive or complementary. Combination therapy decreases the serum concentrations of thyroid hormones in an additive fashion (Kramlinger and Post 1990), whereas lithium-induced increases in leukocytes and neutrophils based on increases in colony-stimulating factor override the common benign decreases in these indices seen with carbamazepine based on suppression of colony-stimulating factor (Kramlinger and Post 1990). It is important to note, however, that lithium cannot alter the course of the rare severe bone marrow suppression caused by carbamazepine (Joffe and Post 1989). In addition, the diuretic effect of lithium overrides the antidiuretic effect of carbamazepine (Klein 1987). Thus, carbamazepine will not reverse lithium-induced diabetes insipidus, although lithium is useful in attenuating carbamazepine-induced hyponatremia (Klein 1987; Vieweg *et al.* 1987). Whether it would also do this for oxcarbazepine, which is even more commonly associated with hyponatremia, is not known.

Reports suggest that the combination of carbamazepine plus **valproate** is not only tolerated but also shows psychotropic synergy (Keck *et al.* 1992; Ketter *et al.* 1992; Tohen *et al.* 1994). Effective combination treatment with these two medications requires knowledge of their drug interactions, which can be simplified with the general principle that usual dosages of carbamazepine should be reduced. Valproate inhibits carbamazepine metabolism (Macphee *et al.* 1988) and displaces carbamazepine from plasma proteins, increasing the free carbamazepine fraction that is active and available to be metabolized (Macphee *et al.* 1988; Moreland *et al.* 1984). Valproate inhibits epoxide hydrolase, increasing the serum carbamazepine-E concentration, which could increase effectiveness or side effects covertly because the increases in carbamazepine-E would not be measured in carbamazepine assays (Brodie *et al.* 1983; Kutt *et al.* 1985; Rambeck *et al.* 1987).

These interactions can potentially confuse clinicians, because patients can experience neurotoxicity from elevated serum carbamazepine-E or free carbamazepine concentrations even if their serum total carbamazepine concentrations are at therapeutic levels (Kutt *et al.* 1985). Carbamazepine decreases serum valproate concentrations (Kondo *et al.* 1990) but increases the formation of the active valproic acid metabolite, 2-propyl-4-pentenoic acid (4-ene-valproic acid [Kondo *et al.* 1990]), which may be hepatotoxic and may add to teratogenicity (Nau and Loscher 1986; Scheffner *et al.* 1988). The risk of fatal hepatitis is of great concern for infants treated with combinations of valproate with other anticonvulsants (Scheffner *et al.* 1988), but this risk is much lower in adults (Dreifuss *et al.* 1989). As a general rule, clinicians should clinically monitor patients receiving the carbamazepine-valproate combination for adverse effects, and they should consider decreasing the carbamazepine dosage in advance of adding valproate and possibly increasing the valproate dosage if needed.

Carbamazepine increases **lamotrigine** metabolism and approximately halves blood lamotrigine concentrations. Thus, lamotrigine dosages can be doubled with this combination.

Carbamazepine induces the metabolism of **carbamazepine** (autoinduction) and **oxcarbazepine** (McKee *et al.* 1994) as well as several older (e.g., ethosuximide, phenytoin, primidone) and newer (e.g., felbamate, **topiramate**) anticonvulsants (Sachdeo *et al.* 1996), tiagabine (Samara *et al.* 1998), and **zonisamide** (Ojemann *et al.* 1986), but not gabapentin (Radulovic *et al.* 1994) or pregabalin (Brodie *et al.* 2005). The enzyme-inducing anticonvulsants phenytoin, phenobarbital, primidone, methsuximide, and felbamate decrease serum carbamazepine levels.

Interactions With Antidepressants

Antidepressants are commonly combined with mood stabilizers in the treatment of bipolar disorder. These drug-drug interactions may be bidirectional.

Fluoxetine (Grimsley *et al.* 1991; Pearson 1990), **fluvoxamine** (Fritze *et al.* 1991), and **nefazodone** (Ashton and Wolin 1996; Laroudie *et al.* 2000; Roth and Bertschy 2001) have been reported to inhibit carbamazepine metabolism, causing increased

carbamazepine concentrations and toxicity. In addition, parkinsonian symptoms have been reported after adding fluoxetine to carbamazepine (Gernaat *et al.* 1991). In contrast, sertraline (Rapeport *et al.* 1996), paroxetine (Andersen *et al.* 1991), citalopram (Moller *et al.* 2001), and mirtazapine (Sitsen *et al.* 2001) do not appear to alter carbamazepine metabolism. Carbamazepine seems to decrease serum concentrations of racemic **citalopram** and **escitalopram** (Steinacher *et al.* 2002). Carbamazepine also appears to induce the metabolism of **mirtazapine** (Sitsen *et al.* 2001), **mianserin** (Eap *et al.* 1999), **sertraline** (Khan *et al.* 2000; Pihlsgard and Eliasson 2002), and (to some extent) trazodone (Otani *et al.* 1996), as well as (most likely) vilazodone (Novartis Pharmaceuticals 2015).

Patients receiving carbamazepine and **bupropion** have low serum bupropion concentrations and high hydroxybupropion (metabolite) concentrations (Ketter *et al.* 1995a), but this is unlikely to be clinically problematic because hydroxybupropion is active. Carbamazepine appears to induce the metabolism of tricyclic antidepressants, including amitriptyline.

Carbamazepine may increase rather than decrease serum levels of transdermal selegiline and its metabolites (Novartis Pharmaceuticals 2015). Theoretical grounds have been stated for concern about combining carbamazepine with monoamine oxidase inhibitors (Thweatt 1986), but case reports (Joffe *et al.* 1985; Yatham *et al.* 1990) and series (Ketter *et al.* 1995b) suggest that the addition of phenelzine or tranylcypromine to carbamazepine may be well tolerated. However, the antituberculosis drug isoniazid, which is also a monoamine oxidase inhibitor, increases carbamazepine levels.

Interactions With Antipsychotics

Combinations of antipsychotics with mood stabilizers are commonly required in severe mania (American Psychiatric Association 2002) and are increasingly used in bipolar maintenance treatment (Ketter 2015; Novartis Pharmaceuticals 2015).

Carbamazepine increases **haloperidol** metabolism (Ereshefsky *et al.* 1986; Jann *et al.* 1989; Kahn *et al.* 1990), dramatically lowering its blood concentrations. However, clinical responses with this combination can be unaffected or even improved (Jann *et al.* 1989; Kahn *et al.* 1990). Weaker evidence suggests that carbamazepine may increase the metabolism of other first-generation antipsychotic agents, including fluphenazine (Ereshefsky *et al.* 1986; Jann *et al.* 1989), chlorpromazine (Raitasuo *et al.* 1994), and thiothixene (Ereshefsky *et al.* 1986), but not thioridazine (Tiihonen *et al.* 1995), and that loxapine, chlorpromazine, and amoxapine may increase carbamazepine-E concentrations (Pitterle and Collins 1988). In view of these interactions, serum antipsychotic medication concentrations should be checked if patients' symptoms do not respond to standard dosages of antipsychotic agents during combined therapy with carbamazepine.

Coadministration of **clozapine** with carbamazepine is not recommended in view of the potential for synergistic bone marrow suppression (Novartis Pharmaceuticals 2015). European centers that have used this drug combination report that carbamazepine decreases clozapine concentrations (Raitasuo *et al.* 1993). Thus, clinicians considering the adjunctive use of a psychotropic anticonvulsant with clozapine should prescribe valproate or another anticonvulsant rather than carbamazepine, except under unusual circumstances.

Carbamazepine increases the metabolism of **olanzapine** (Linnet and Olesen 2002; Lucas *et al.* 1998), **risperidone** (Ono *et al.* 2002; Spina *et al.* 2000; Yatham *et al.* 2003),

quetiapine (Grimm *et al.* 2006), **aripiprazole** (Novartis Pharmaceuticals 2015), **ziprasidone** (Miceli *et al.* 2000), and possibly lurasidone, brexpiprazole, cariprazine, and lumateperone; therefore, dosages of these atypical antipsychotics may need to be increased (Tohen *et al.* 2008; Yatham *et al.* 2003).

Interactions With Anxiolytics and Sedatives

Carbamazepine is commonly coadministered with **benzodiazepines**, with merely additive CNS adverse effects (e.g., sedation, ataxia). Carbamazepine may decrease serum levels of clonazepam (Lai *et al.* 1978; Yukawa *et al.* 2001), alprazolam (Arana *et al.* 1988; Furukori *et al.* 1998), clobazam (Levy *et al.* 1983), and midazolam (Backman *et al.* 1996), potentially decreasing the efficacy of these agents. The newer hypnotics eszopiclone and zolpidem, which are susceptible to drug interactions involving induction of CYP3A4, may have drug interactions with carbamazepine (Drover 2004). Of interest, carbamazepine may be effective in ameliorating benzodiazepine withdrawal symptoms (Ries *et al.* 1989).

Interactions With Stimulants

Armodafinil and carbamazepine combination treatment may decrease armodafinil levels by 37% and carbamazepine levels by 25% (Darwish *et al.* 2015).

Interactions With Calcium Channel Blockers

Of clear clinical importance, elevated serum carbamazepine concentrations and neurotoxic effects have been reported during concurrent treatment with the nondihydropyridines **verapamil** and **diltiazem** but not with the dihydropyridines nifedipine (Brodie and MacPhee 1986; Price and DiMarzio 1988) and nimodipine. These observations are consistent with the finding that verapamil and diltiazem, but not nifedipine, inhibit the hepatic oxidative metabolism of various drugs (Hunt *et al.* 1989). Enzyme-inducing anticonvulsants like carbamazepine appear to decrease serum concentrations of **dihydropyridines** such as nimodipine (Tartara *et al.* 1991) and felodipine (Capewell *et al.* 1988; Zaccara *et al.* 1993).

Interactions With Substances of Abuse

Ethanol and carbamazepine do not interact pharmacokinetically (Dar *et al.* 1989; Pynnonen *et al.* 1978). However, carbamazepine attenuates alcohol withdrawal symptoms (Malcolm *et al.* 1989). Disulfiram combined with carbamazepine is well tolerated and does not cause clinically significant changes in serum carbamazepine and carbamazepine-E concentrations (Krag *et al.* 1981). Cigarette smoking does not alter carbamazepine metabolism (Bachmann *et al.* 1990), and carbamazepine does not alter caffeine pharmacokinetics (Wietholtz *et al.* 1989).

Interactions With Nonpsychotropic Drugs

Carbamazepine induces the metabolism of diverse medications, raising the possibility of undermining the efficacy of **steroids** (contraceptives, dexamethasone, mifepristone), **methylxanthines** (theophylline, aminophylline), antibiotics (**doxycycline**), **protease inhibitors**, **neuromuscular blockers** (pancuronium, vecuronium, doxacurium), analgesics (**methadone**), **immunosuppressants** (sirolimus, tacrolimus), the anticoagulant **warfarin**, and possibly dicumarol (see Table 39-4). For women taking carbamazepine, dosages of oral contraceptive preparations may need to be adjusted to ensure continued efficacy (Crawford 2002).

Similarly, a variety of medications can increase serum carbamazepine concentrations and cause clinical toxicity. Such medications include **isoniazid**, **azole antifungals** (ketoconazole), **macrolide antibiotics** (erythromycin and clarithromycin), **protease inhibitors** (ritonavir and nelfinavir), **hypolipidemics** (gemfibrozil and nicotinamide), and the carbonic anhydrase inhibitor **acetazolamide** (see Table 39-5). In addition, other medications such as cisplatin and doxorubicin may decrease serum carbamazepine levels, potentially leading to inefficacy.

Oxcarbazepine

Compared with carbamazepine, oxcarbazepine has fewer clinically significant drug-drug interactions. Differences in three major areas seem to contribute importantly to differences between oxcarbazepine and carbamazepine with regard to drug-drug interactions.

1. **Oxcarbazepine is only a modest to moderate enzyme (CYP3A4) inducer, which yields clinically significant decreases in serum concentrations of some medications** (see Table 39-4). Oxcarbazepine yields minor enzyme heteroinduction (but not autoinduction), which is clearly less robust than that seen with carbamazepine, but the effect may be clinically significant for some medications (in *italics* in Table 39-4).
2. **Oxcarbazepine metabolism (which is primarily by arylketone reductase) is not generally susceptible to enzyme inhibitors.** The absence of autoinduction and the robust actions of cytosol reductases that mediate conversion to MHD

appear to render oxcarbazepine metabolism not susceptible to the common phenomenon of inhibition by other agents seen with carbamazepine. Thus, the medications listed in Table 39-5 that can elevate serum carbamazepine concentrations and cause neurotoxicity do not appear to have such interactions with oxcarbazepine.

3. **Oxcarbazepine has an active (MHD) metabolite** (see Figure 39-1, bottom middle). MHD metabolism, unlike carbamazepine-E catabolism, is not inhibited by valproate, presumably because of the lack of involvement of epoxide hydrolase in MHD disposition. Thus, coadministration of valproate with oxcarbazepine does not result in toxicity related to increased MHD.

Interactions With Mood Stabilizers and Anticonvulsants

Oxcarbazepine, in contrast with carbamazepine, does not induce valproate metabolism and seems to have less robust effects on **lamotrigine** metabolism (May *et al.* 1999). Oxcarbazepine may modestly decrease serum concentrations of topiramate (May *et al.* 2002) and levetiracetam (May *et al.* 2003). In addition, oxcarbazepine can increase serum phenytoin concentrations, presumably by inhibiting CYP2C19 activity. The anticonvulsants phenytoin, phenobarbital, primidone, and carbamazepine may induce oxcarbazepine metabolism, yielding decreased serum MHD concentrations (McKee *et al.* 1994).

Interactions With Antidepressants

Oxcarbazepine, in contrast with carbamazepine, does not robustly induce citalopram metabolism.

Interactions With Antipsychotics

Oxcarbazepine, unlike carbamazepine, does not robustly induce antipsychotic metabolism.

Interactions With Anxiolytics and Sedatives

Oxcarbazepine may decrease serum concentrations of **benzodiazepines**.

Interactions With Calcium Channel Blockers

Oxcarbazepine appears to decrease serum concentrations of **dihydropyridine** calcium channel blockers (which are CYP3A4 substrates) to some extent.

Interactions With Nonpsychotropic Drugs

Oxcarbazepine, compared with carbamazepine, also seems to have fewer interactions with nonpsychotropic drugs. Thus, neither the CYP3A4 inhibitor erythromycin (Keranen *et al.* 1992a) nor the heteroinhibitor cimetidine (Keranen *et al.* 1992b) appears to alter oxcarbazepine pharmacokinetics in healthy volunteers.

However, oxcarbazepine seems to have a clinically significant interaction with **hormonal contraceptives**. In healthy female volunteers, oxcarbazepine appeared to decrease ethinylestradiol and levonorgestrel derived from hormonal contraceptives by as much as 50% (Fattore *et al.* 1999; Kramer *et al.* 1992), such that use of higher-dosage forms of estrogen-related oral contraceptives may be indicated.

Like carbamazepine, oxcarbazepine may decrease serum concentrations of the analgesic buprenorphine, the anticancer agent paclitaxel, and the antidiabetic agent repaglinide. Oxcarbazepine also yields decreases in serum concentrations of the dihydropyridine calcium channel blocker felodipine, which is also a CYP3A4 substrate. In contrast with carbamazepine, the CYP3A4 inhibitor erythromycin and the antidepressant viloxazine do not yield clinically significant increases in serum oxcarbazepine concentrations.

Eslicarbazepine Acetate

Eslicarbazepine acetate, which shares the same active metabolite as oxcarbazepine, also has fewer clinically significant drug-drug interactions compared with carbamazepine. Eslicarbazepine acetate is modestly protein bound, without significant related interactions. This drug does not have significant effects on most CYP enzyme pathways, including CYP1A2, CYP2A6, CYP2B6, CYP2C9, CYP2D6, CYP2E1, and CYP4A9/11 (Almeida and Soares-da-Silva 2007). Its three main pharmacokinetic effects are weak induction of CYP3A4, weak induction of uridine 5'-diphosphoglucuronosyltransferases, and weak inhibition of CYP2C19 (Zaccara *et al.* 2015).

Interactions With Mood Stabilizers

Similar to oxcarbazepine and in contrast with carbamazepine, eslicarbazepine acetate does not significantly induce valproate metabolism. Moreover, eslicarbazepine acetate does not have significant interactions with lamotrigine or topiramate metabolism (Bialer and Soares-da-Silva 2012).

Interactions With Nonpsychotropic Drugs

Because of its modest induction of CYP3A4 activity, eslicarbazepine acetate may induce moderate reductions in estradiol (up to 42%) in a possibly dose-dependent interaction, potentially reducing the effectiveness of oral contraceptives (Bialer and Soares-da-Silva 2012). Simvastatin levels may be decreased by up to 40% with eslicarbazepine acetate coadministration, presumably as a function of CYP3A4 induction (Zaccara *et al.* 2015).

Practical Clinical Principles for Use of Carbamazepine and Oxcarbazepine

Because blood levels of carbamazepine do not correlate with the degree of clinical response to carbamazepine in either mood disorders (Post *et al.* 2007) or epilepsy, and blood levels associated with toxicity vary widely among patients (Tomson 1984), upward titration of the carbamazepine dose should proceed slowly to minimize side effects and maximize effectiveness. That is, dose titration can be accomplished with minimal blood level monitoring.

There are now long-acting preparations of both carbamazepine (Equetro and Carbatrol) and oxcarbazepine (Oxtellar). Clinical studies in patients with mood disorders, as opposed to epilepsy, support the use of single nighttime doses to maximize effects on sleep and minimize daytime side effects. This approach also simplifies the regimen and enhances compliance.

Conclusion

Because of the past lack of an FDA indication, complexity of use, and methodological concerns regarding earlier efficacy studies, carbamazepine was generally considered an alternative rather than a first-line intervention in bipolar disorder. However, the approval of a proprietary carbamazepine beaded extended-release capsule formulation (Equetro) for the treatment of acute manic and mixed episodes in patients with bipolar disorder and the low propensity of carbamazepine to cause the weight gain and metabolic problems seen with some other agents may lead clinicians to reassess the role of this agent in the management of bipolar disorder (Ketter 2015).

Oxcarbazepine has more limited evidence of efficacy in bipolar disorder compared with carbamazepine, but it has good tolerability (except for an increased incidence of hyponatremia) and fewer drug-drug interactions. Some data suggest that oxcarbazepine is less effective than carbamazepine in severe or psychotic mania. MHD (the active metabolite of oxcarbazepine) and eslicarbazepine acetate (the prodrug to the *S*-enantiomer of MHD) likewise have enhanced tolerability and fewer drug-drug interactions, but their efficacy in bipolar disorder remains to be established.

With carbamazepine but not oxcarbazepine, common benign leukopenia (which can be reversed with lithium) may occur and must be distinguished from rare serious aplastic anemia. Physicians and caregivers must alert patients to symptoms of this adverse effect (e.g., fever, sore throat, petechiae) so that a complete blood count can be performed rapidly. In addition, carbamazepine--and to a lesser extent, oxcarbazepine--in combination therapy induces the metabolism of other drugs, especially the atypical antipsychotics, which suggests that dosages may need to be increased accordingly. Other commonly used drugs (e.g., erythromycin, verapamil) can inhibit carbamazepine (but not oxcarbazepine) metabolism, causing carbamazepine toxicity. Instructing patients to alert their other caregivers and their pharmacist that they are receiving carbamazepine may help avoid drug interactions.

Carbamazepine is an important treatment option for patients with bipolar disorder who experience an inadequate response or unacceptable adverse effects with lithium and valproate. Awareness of carbamazepine and oxcarbazepine pharmacology and potential drug-drug interactions will enable clinicians to provide the safest and most effective care for their patients with bipolar disorder.

CHAPTER 40

Gabapentin and Pregabalin

Mark A. Frye, M.D.
Katherine Marshall Moore, M.D.
Alan F. Schatzberg, M.D.

In this chapter we review background information, pharmacological profiles, clinical indications, adverse events, and other considerations for two anticonvulsant agents, gabapentin and pregabalin.

Gabapentin

Early observations of enhanced general well-being in patients with epilepsy treated with anticonvulsants, as well as various early hypotheses of kindling and sensitization proposed as models of affective illness progression (Weiss and Post 1998), have promoted controlled investigations of anticonvulsant drugs as potential mood-stabilizing agents.

Gabapentin is FDA approved for the adjunctive treatment of complex partial epilepsy in pediatric patients ages 3-12 years and individuals older than 12 years (with and without secondary generalization) and for the management of postherpetic neuralgia in adults. A retrospective review of five placebo-controlled trials of gabapentin in more than 700 patients with refractory partial seizure disorder additionally supported the concept of improvement in general well-being, prompting controlled investigation of the drug in primary psychiatric conditions (Dimond *et al.* 1996).

Structure-Activity Relations

Gabapentin (2-[1-(aminomethyl)cyclohexyl]acetic acid) is a synthetic analog of GABA (Figure 40-1).

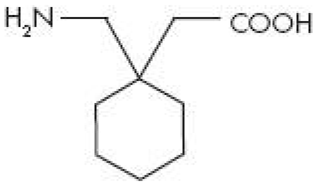

FIGURE 40-1. Chemical structure of gabapentin.

Pharmacological Profile and Mechanism of Action

The mechanism of gabapentin's anticonvulsant and psychotropic action is not fully understood. Gabapentin was originally developed as a GABA analog. As reviewed by Taylor *et al.* (1998), GABA is the major inhibitory neurotransmitter in the cerebral cortex. Preclinical studies have suggested that gabapentin increases brain and intracellular GABA by an amino acid active transporter at the blood-brain barrier and multiple enzymatic regulatory mechanisms, respectively. In vitro, gabapentin increases the activity of glutamic acid decarboxylase, the enzyme that converts glutamate to GABA (Taylor *et al.* 1992). Conversely, gabapentin has been shown to inhibit GABA transaminase, the enzyme primarily responsible for GABA catabolism (Loscher *et al.* 1991). Glutamate metabolism is also modulated by gabapentin. In vitro, gabapentin inhibits branched-chain amino acid aminotransferase, which is responsible for glutamate synthesis (Hutson *et al.* 1998); gabapentin also activates glutamate dehydrogenase, which is involved in glutamate catabolism (Goldlust *et al.* 1995).

These enzymatic regulatory mechanisms that suggest increased synthesis and decreased degradation of GABA are clinically relevant. Several but not all studies have reported decreased levels of cerebrospinal fluid (Goddard *et al.* 1996; Gold *et al.* 1980; Roy *et al.* 1991), plasma (Petty *et al.* 1990), and magnetic resonance spectroscopic GABA (Sanacora *et al.* 1999) in patients with affective illness compared with healthy control subjects. Furthermore, increased magnetic resonance spectroscopic occipital GABA concentrations have been reported with serotonin reuptake inhibitor treatment in patients with depression (Sanacora *et al.* 2002) and gabapentin treatment in patients with complex partial epilepsy (Petroff *et al.* 1996).

Gabapentin also has been shown to bind to the a_2 subunit receptor of brain voltage-dependent calcium channels, an effect that may relate to the subsequent inhibition of monoaminergic transmission (Schlicker *et al.* 1985). There is no known direct activity at dopamine, serotonin, benzodiazepine, or histamine receptors. However, gabapentin has been reported to increase whole-blood levels of serotonin in healthy control subjects (Rao *et al.* 1988).

Formulations

Gabapentin is available in multiple dosage forms, including oral capsules (100, 300, and 400 mg), tablets (100, 300, 400, 600, and 800 mg), and an oral solution (250 mg/5 mL), and generic equivalent products are available (Pfizer 2017). For patients who cannot ingest capsules or tablets, the capsule products may be opened and sprinkled on food. A gabapentin enacarbil oral extended-release tablet (300 and 600 mg) is also available in the United States (Arbor Pharmaceuticals 2020). The FDA-approved indications for this product include treatment, in adults, of moderate to severe primary restless legs syndrome and management of postherpetic neuralgia (Arbor Pharmaceuticals 2020).

Pharmacokinetics and Disposition

All bioavailability, distribution, and elimination parameters are based on the gabapentin molecule itself, as there is no active metabolite. Gabapentin exhibits nonlinear bioavailability most likely related to an active saturable

L-amino acid transport carrier present in the gut and blood-brain barrier (McLean 1999). Gabapentin may be taken without regard to mealtimes, as food does not significantly affect the rate or extent of absorption. The alternative enacarbil formulation produces more consistent absorption and/or transport in the gastrointestinal tract, and this formulation should be administered with food, which enhances absorption (Arbor Pharmaceuticals 2020). There is no evidence of plasma protein binding, hepatic metabolism, or cytochrome P450 (CYP) autoinduction. The elimination half-life is 6-8 hours, with a recommended three-times-a-day dosing strategy. Gabapentin is eliminated from the systemic circulation unchanged by renal excretion. Patients with compromised renal function will show evidence of reduced gabapentin clearance.

Indications and Efficacy

Epilepsy

Gabapentin currently is FDA approved for use in the adjunctive treatment of partial seizures with and without secondary generalization in adults and pediatric patients 3 years and older with epilepsy (Pfizer 2017). Approval for this indication was based on controlled evaluations of gabapentin at daily dosages of 600-1,800 mg. Additional research has reported efficacy and tolerability for gabapentin monotherapy at daily dosages up to 4,800 mg in patients with refractory epilepsy (Beydoun *et al.* 1998). There is no established therapeutic plasma level for seizure control. Gabapentin has a highly favorable side-effect profile, with only mild side effects (sedation, dizziness, and ataxia) commonly reported.

Nonepilepsy Neurological Conditions

Neuropathic pain. Gabapentin received FDA approval for use in the management of postherpetic neuralgia in adults on the basis of two placebo-controlled studies (Rice *et al.* 2001; Rowbotham *et al.* 1998). Gabapentin also has been systematically evaluated in diabetic neuropathy (Backonja *et al.* 1998).

The initial postherpetic neuralgia (Rowbotham *et al.* 1998) and diabetic neuropathy (Backonja *et al.* 1998) studies were randomized, double-blind, placebo-controlled, parallel-group multicenter investigations with three phases of evaluation. The first phase identified the subject population, which comprised patients with a diabetic neuropathy duration of 1-5 years (Backonja *et al.* 1998) or postherpetic neuralgia duration of 3 months (Rowbotham *et al.* 1998). The 8-week double-blind phases consisted of a 4-week step titration (900, 1,800, 2,400, and 3,600 mg/day for weeks 1-4, respectively) and a 4-week fixed-dosage period wherein the dosage that was effective and tolerable from the titration phase was held constant. There were no differences in demographics or rates of dropout due to inefficacy or adverse events between the gabapentin group and the placebo group.

Among the 229 patients with postherpetic neuralgia (Rowbotham *et al.* 1998), greater pain reduction occurred with gabapentin, which was noted as early as week 2 and maintained throughout the entire study period. Similarly, secondary measures of mood, such as depression, anger/hostility, fatigue/inertia, and physical functioning, were treated more effectively with gabapentin than with placebo. Improvement was maintained for 83% of patients receiving gabapentin 2,400 mg/day and for 65% of individuals taking 3,600 mg/day.

Among the 165 patients with diabetic neuropathy (Backonja *et al.* 1998), greater pain reduction (as measured with an 11-point Likert scale) occurred with gabapentin than with placebo. This difference was statistically significant as early as week 2 of the blind titration phase and remained significant for the duration of the 8-week study. Significant reductions in sleep interference related to pain as well as improved quality of life were also reported. Gabapentin appeared to be well tolerated, with improvement for 67% of the patient group continued on a maximum daily dosage of 3,600 mg.

Finally, a 7-week placebo-controlled study evaluated gabapentin (1,800 or 2,400 mg/day in three divided doses) in 334 patients with postherpetic neuralgia (Rice *et al.* 2001). Pain was significantly reduced with both gabapentin dosages, with similar improvements in sleep. An improvement in pain score was noted as early as week 1 and was maintained throughout the study.

These results contrast with findings of additional studies that have investigated gabapentin's utility in the management of perioperative pain (Zhang *et al.* 2015). In a reanalysis of two randomized controlled trials of adjunctive gabapentin versus adjunctive placebo in patients undergoing total knee (*n* = 102) or total hip arthroplasty (*n* = 101), gabapentin did not significantly reduce the primary outcome measure of morphine consumption immediately postprocedure and 24, 48, and 72 hours postsurgery.

Movement disorders (off-label). Controlled investigations of gabapentin have been conducted in several movement disorders. These studies were much smaller than the neuropathic pain studies mentioned in the prior section but included amyotrophic lateral sclerosis (Miller *et al.* 1996), essential tremor (Ondo *et al.* 2000; Pahwa *et al.* 1998), and parkinsonism (Olson *et al.* 1997).

In a study of 152 patients with amyotrophic lateral sclerosis, participants were randomly assigned to gabapentin 2,400 mg/day or placebo for 6 months. Decline in muscle strength, the primary outcome measure, occurred more slowly in the gabapentin-treated patients than in the placebo-treated patients (Miller *et al.* 1996).

Controlled studies of gabapentin for essential tremor have reported mixed results. The first controlled study lasted 2 weeks and showed no difference between gabapentin 1,800 mg/day and placebo for treatment of essential tremor (Pahwa *et al.* 1998). A second controlled study, a 6-week evaluation of two gabapentin dosages (1,800 and 3,600 mg/day) in patients with essential tremor, demonstrated significantly greater improvements in self-report scores, observed tremor scores, and activities of daily living scores for individuals randomly assigned to gabapentin compared with placebo (Ondo *et al.* 2000).

In a 1-month double-blind, placebo-controlled evaluation of gabapentin in 19 patients with advanced parkinsonism, gabapentin at a mean total dosage of 1,200 mg/day was superior to placebo in reducing rigidity, bradykinesia, and tremor, as measured by the Unified Parkinson's Disease

Rating Scale (Olson *et al.* 1997). The improvements in rigidity and bradykinesia were independent of tremor improvement.

Finally, trials have shown positive results for gabapentin in the treatment of restless legs syndrome, particularly with the proprietary enacarbil formulation at dosages of 300-1,200 mg/day (Yaltho and Ondo 2010).

Migraine headache (off-label) Comorbid migraine headache and bipolar disorder is highly prevalent and clinically significant (Mahmood *et al.* 1999). Because of their mood-stabilizing effects and migraine prophylactic properties, anticonvulsants seem to be ideal in this patient population. Mathew *et al.* (2001) suggested that gabapentin is an effective agent for migraine prophylaxis. This three-phase controlled evaluation of gabapentin included 143 patients with migraine (with and without aura). Phase 1 was a 4-week single-blind placebo period during which baseline migraine headache frequency was established. Phase 2 was a 4-week double-blind, placebo-controlled, flexible-dosage titration period during which patients received gabapentin at dosages up to 2,400 mg/day. Phase 3 was an 8-week double-blind, placebo-controlled period during which the dosage of gabapentin was held constant. Patients randomly assigned to gabapentin 2,400 mg/day had significantly greater reductions in migraine attacks compared with placebo-treated patients. Dropout rates were higher with gabapentin and were primarily related to drowsiness and somnolence.

Psychiatric Disorders

Gabapentin is commonly used off-label for psychiatric disorders. This use is seen more commonly in primary care than in psychiatry settings (Costales and Goodin 2021), with patients also using antidepressants, benzodiazepines, and opioids.

Anxiety disorders (off-label). Gabapentin produces a dose-dependent anxiolytic response in animal models (Singh *et al.* 1996). Open-trial investigations have reported positive results with add-on gabapentin in the treatment of generalized anxiety disorder (Pollack *et al.* 1998), panic disorder (Pollack *et al.* 1998), and refractory OCD (Cora-Locatelli *et al.* 1998). Findings from controlled investigations of gabapentin in social anxiety disorder (i.e., DSM-IV social phobia) (Pande *et al.* 1999) and panic disorder (Pande *et al.* 2000b) suggested that gabapentin has anxiolytic activity.

Pande *et al.* (1999) conducted a 14-week randomized, double-blind, placebo-controlled, two-site study of 69 outpatients with DSM-IV-confirmed social phobia (American Psychiatric Association 1994). All patients were required to have a score of 50 or greater on the Liebowitz Social Anxiety Scale (LSAS) at baseline. Reductions in LSAS scores served as the primary outcome measure. In the intent-to-treat analysis, gabapentin was more effective than placebo in reducing social anxiety symptoms. The dosage range for gabapentin was 900-3,600 mg/day, and 56% of patients reported symptom response and tolerability with the maximum daily dosage of 3,600 mg. Dizziness and dry mouth were significantly more common in patients treated with gabapentin.

The second study was an 8-week randomized, placebo-controlled, six-site monotherapy study of 103 patients with DSM-IV-confirmed panic disorder with or without agoraphobia (Pande *et al.* 2000b). Gabapentin was dosed flexibly between 600 and 3,600 mg/day. The primary outcome measure was a decrease in Panic and Agoraphobia Scale (PAS) score. There were no differences in dropout rates between the gabapentin and placebo groups. In the intent-to-treat analysis, no difference in PAS score reduction was seen between patients randomly assigned to gabapentin and those receiving placebo. In a post hoc stratification of high ([?] 20) and low (< 20) PAS symptom severity, patients with high symptom severity who were randomly assigned to gabapentin had a greater decrease in PAS score from baseline to endpoint than did those who received placebo. Somnolence, headache, dizziness, infection, asthenia, and ataxia were more common with gabapentin than with placebo.

Bipolar disorder (off-label). Numerous case reports on and open trials of gabapentin as a mood stabilizer--encompassing more than 400 patients with a pooled response rate between 65% and 70%--have been reviewed elsewhere (Frye *et al.* 2000; Yatham *et al.* 2002).

One double-blind, placebo-controlled outpatient study evaluated add-on gabapentin for the treatment of bipolar I disorder with manic, hypomanic, or mixed symptoms (Pande *et al.* 2000a). The first phase of the study involved a 2-week single-blind placebo lead-in wherein dosages of the patient's primary mood stabilizer (lithium or valproate) could be adjusted to maximal clinical benefit and a minimum threshold of therapeutic level (i.e., lithium 0.5 mmol/L, valproate > 50 mg/mL). The second phase was a 10-week double-blind trial in which participants were randomly assigned to gabapentin at flexible dosages between 600 and 3,600 mg/day (taken in three divided doses) or to placebo. In the intent-to-treat population, 117 subjects were randomly assigned to treatment; no differences in demographic profile or dropout rate were found between the two groups. The primary outcome measure (total decrease in score on the Young Mania Rating Scale) was significantly different between groups in favor of add-on placebo. In a post hoc analysis, it was observed that lithium adjustments in the single-blind placebo lead-in phase were made more frequently in the placebo group than in the gabapentin group; most of these adjustments (9 of 12 [75%]) consisted of a dosage increase. This fact suggests either a strong placebo response or the effect of maximizing lithium blood levels to achieve a greater antimanic response. Of the gabapentin-treated patients who had drug levels measured, nearly 20% had plasma gabapentin levels that were undetectable.

The second controlled study was a 6-week double-blind, placebo-controlled crossover comparative trial of gabapentin monotherapy, lamotrigine monotherapy, and placebo in 35 inpatients with refractory mood disorder (Frye *et al.* 2000; Obrocea *et al.* 2002). In the preliminary (Frye *et al.* 2000) and final (Obrocea *et al.* 2002) analyses, gabapentin demonstrated no better treatment response than placebo in a group of patients with highly refractory bipolar (primarily rapid-cycling) disorder.

There seems to be a marked contrast between the pooled results of the uncontrolled observations (generally positive) and the results of the controlled studies (generally negative). Important limitations of the controlled investigations included maximizing lithium response in the single-blind placebo run-in phase, lack of rigorous compliance assessment, and use of a monotherapy study design in a cohort of patients with primarily rapid-cycling, treatment-refractory illness.

Substance-related disorders (off-label). Mood-stabilizing anticonvulsants such as divalproex sodium and carbamazepine may be useful in the treatment of alcohol abuse in bipolar disorder (Malcolm *et al.* 2001). Gabapentin has been shown to reduce excitability and convulsions in animal models of alcohol withdrawal (Watson *et al.* 1997). Its lack of hepatic metabolism, CYP enzyme induction, protein binding, and addictive potential make gabapentin a potentially useful compound in this patient population.

Gabapentin's potential utility in the treatment of alcohol withdrawal was examined after initial positive reports emerged (Bozikas *et al.* 2002). One study demonstrated

that gabapentin had efficacy comparable to that of phenobarbital in treating alcohol withdrawal (Mariani *et al.* 2006), although another controlled trial did not substantiate gabapentin's benefit over placebo (Bonnet *et al.* 2003). In a post hoc analysis (Bonnet *et al.* 2007), there was a significantly greater increase in the Profile of Mood States vigor subscore in the gabapentin group versus the placebo group; this response was particularly robust in patients with comorbid mild depression.

Despite the conflicting findings regarding gabapentin's efficacy in alcohol withdrawal, its therapeutic benefit in the sleep-disturbance component of alcohol withdrawal syndrome is now recognized. In a study in outpatients with DSM-IV-confirmed alcohol dependence who were experiencing persistent insomnia (Karam-Hage and Brower 2003), low-dose gabapentin (mean 900 mg at bedtime) was associated with greater improvement in sleep problems compared with trazodone, as assessed with the Sleep Problems Questionnaire. In another study, gabapentin was associated with significantly greater reductions in self-reported sleep disturbances and daytime sleepiness in outpatients being treated for alcohol withdrawal compared with lorazepam (Malcolm *et al.* 2007).

A 4-week randomized, placebo-controlled, double-blind study evaluated gabapentin utility in the prevention of alcohol use relapse (Furieri and

Nakamura-Palacios 2007). After detoxification, 60 men with DSM-IV-confirmed alcohol dependence who had been consuming on average 17 drinks per day for the preceding 3 months were randomly assigned to gabapentin (300 mg bid) or placebo. The gabapentin group showed significant reductions in number of drinks per day, percentage of heavy drinking days, and craving for alcohol (specifically automaticity of drinking) as well as an increase in percentage of days abstinent. In a study in 150 individuals with DSM-IV-confirmed alcohol dependence, the addition of gabapentin to naltrexone was reported to significantly improve drinking outcomes compared with naltrexone alone or placebo (Anton *et al.* 2011). Another clinical trial examined linear dose effects of gabapentin on alcohol-related insomnia, dysphoria, and craving in patients with DSM-IV-confirmed alcohol dependence (Mason *et al.* 2014). In this 12-week randomized double-blind trial (*n* = 150), evidence of a linear dose response (gabapentin 1,800 mg > gabapentin 900 mg > placebo) was found for abstinence, absence of heavy drinking (defined as [?] 4 and [?] 5 drinks/day for women and men, respectively), mood (i.e., improvement), sleep (i.e., sleep quality), and craving (i.e., reduction).

In a more recent randomized clinical trial in patients with alcoholism, gabapentin was significantly more effective than placebo in decreasing heavy drinking days and heavy alcohol use, with greater pretreatment alcohol withdrawal symptoms predicting a good response (Anton *et al.* 2020). In their meta-analysis of gabapentin, Kranzler *et al.* (2019) also noted statistically significant benefit for gabapentin in deceasing the percentage of heavy alcohol use days.

Finally, in a proof-of-concept randomized controlled study in 50 treatment-seeking outpatients with DSM-IV-confirmed cannabis dependence, gabapentin 1,200 mg/day was significantly more effective than placebo in reducing cannabis use and decreasing withdrawal symptoms (Mason *et al.* 2012).

Side Effects and Toxicology

Gabapentin has a highly favorable side-effect profile that has been remarkably consistent across controlled studies of diverse disease states. Sedation, drowsiness, and dizziness have long been reported. Ataxia, dry mouth, infection, and asthenia have been reported in at least one placebo-controlled study.

Adverse events caused by gabapentin are uncommon but can have serious psychiatric implications. Gabapentin-induced hypomania and mania have been reported (Leweke *et al.* 1999; Short and Cooke 1995). The controlled study in mania did not report data on the percentage of patients experiencing exacerbation of mania secondary to gabapentin treatment (Pande *et al.* 2000a). Gabapentin also has been associated with aggression, both in pediatric epilepsy (Wolf *et al.* 1995) and in adult mania (Pinninti and Mahajan 2001).

Gabapentin has a broad therapeutic index and appears to be safe in overdose. The broadness of the therapeutic index is most likely related to its nonlinear bioavailability secondary to a saturable transport carrier (McLean 1999).

The drug appears to be abusable, as seen in a number of published case series and epidemiological surveys (Evoy *et al.* 2017; Mersfelder and Nichols 2016), with greater rates of misuse seen in substance abuse settings.

Drug-Drug Interactions

Given its lack of hepatic metabolism, absence of CYP autoinduction, and minimal plasma protein binding, gabapentin does not affect levels of anticonvulsant drugs; similarly, gabapentin's pharmacokinetic characteristics do not change when the drug is coadministered with hepatically metabolized anticonvulsants (Pfizer 2017). However, gabapentin's renal excretion does pose a potential risk when the drug is used concomitantly with lithium.

Although the therapeutic index for gabapentin is large, the safety window for lithium is not. In a pharmacokinetic study examining the effect of gabapentin versus placebo on a single 600-mg dose of lithium, there was no difference in maximum lithium concentration, time to reach the maximum lithium concentration, or area under the curve (AUC) in 13 patients receiving steady-state gabapentin (mean dose of 3,645.15 +- 931.5 mg) compared with those receiving steady-state placebo (Frye *et al.* 1998).

It is important to emphasize that this study was conducted in a patient population with normal renal function; cases of reversible renal impairment associated with gabapentin have been reported (Grunze *et al.* 1998).

Summary for Gabapentin

Results of controlled studies of gabapentin clearly suggest its efficacy in several medical conditions, including complex partial epilepsy, postherpetic neuropathy, restless legs syndrome, diabetic neuropathy, and migraine headache. Data also clearly suggest gabapentin's benefit in several off-label psychiatric uses such as substance-related abstinence or craving, mood disorders, and some anxiety disorders. Conclusions regarding gabapentin's efficacy in amyotrophic lateral sclerosis, essential tremor, parkinsonism, social anxiety disorder, or panic disorder are less clear, either because of positive controlled studies with small sample sizes or because of negative studies. Its role as a mood stabilizer is not clearly established. Gabapentin has a favorable pharmacokinetic profile, and its lack of hepatic metabolism is a particular advantage in patients with compromised liver function. Its minimal drug-drug interactions, low risk of toxicity, and benign side-effect profile make gabapentin a useful addition to the pharmacopoeia.

Pregabalin

Pregabalin is an anticonvulsant drug approved by the FDA for the adjunctive treatment of partial-onset seizures in adults. It is also approved for the treatment of neuropathic pain associated with diabetic peripheral neuropathy, postherpetic neuralgia, and fibromyalgia. Like many of the newer anticonvulsant agents, pregabalin has been evaluated in carefully controlled studies for possible utility in neurological and psychiatric conditions other than primary epilepsy.

Structure-Activity Relations

Pregabalin [(3S)-3-(aminomethyl)-5-methylhexanoic acid] is a synthetic analog of GABA (Figure 40-2).

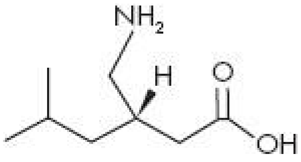

FIGURE 40-2. Chemical structure of pregabalin.

Pharmacological Profile and Mechanism of Action

Pregabalin, like gabapentin, is a structural analog of the inhibitory neurotransmitter GABA. Pregabalin showed greater potency than gabapentin in preclinical models of epilepsy, pain, and anxiety (Hamandi and Sander 2006). Despite being a GABA structural analog, pregabalin has no clinically significant effect at either the $GABA_A$ or the $GABA_B$ receptor and is not converted metabolically into GABA or a GABA agonist (Kavoussi 2006). Furthermore, pregabalin does not bind to any serotonergic, dopaminergic, or glutamatergic receptors. It does bind to the a_2d subunit of the presynaptic voltage-gated calcium channel, modulating the release of excitatory neurotransmitters (Dooley *et al.* 2002; Kavoussi 2006). In contrast with GABA reuptake-inhibitory anticonvulsants (e.g., tiagabine) or anticonvulsants that modulate enzymatic activity related to GABA production (e.g., vigabatrin), pregabalin has no direct GABA reuptake-inhibitory effects or GABA transaminase-inhibiting effects.

Formulations

Pregabalin is available in multiple dosage forms (Pfizer 2018; 2020), including oral capsules (25, 50, 75, 100, 150, 200, 225, and 300 mg), extended-release tablets (82.5, 165, and 330 mg), and an oral solution (100 mg/5 mL). Generic equivalent products are also available.

Pharmacokinetics and Disposition

Pregabalin exhibits linear pharmacokinetics and is not associated with any significant protein binding or hepatic metabolism. Immediate-release pregabalin products have an oral bioavailability that is greater than 90% and independent of dose. With immediate-release pregabalin products, steady-state plasma levels are generally achieved within 24-48 hours, and administration with food has no clinically significant effect on the extent of absorption or on elimination (Pfizer 2018). The elimination half-life of the drug is approximately 6.5 hours (Montgomery 2006). Because pregabalin is highly lipophilic but not bound to plasma proteins, it readily crosses the blood-brain barrier. Pregabalin is primarily (> 90%) excreted renally unchanged, with no active metabolites. Dosage adjustment is required for patients with renal impairment.

Pregabalin does not induce or inhibit CYP enzymes, nor do CYP enzyme inhibitors alter its pharmacokinetics. The bioavailability of pregabalin extended-release tablets is reduced if they are taken on an empty stomach (Pfizer 2020). The AUC is approximately 30% lower when tablets are taken on an empty stomach than when taken after an evening meal. With repeated administration (in which each new dose is taken before elimination of the previous dose), steady state is achieved within approximately 48-72 hours.

Indications and Efficacy

Epilepsy

Several placebo-controlled studies have evaluated pregabalin in the treatment of patients with refractory partial epilepsy (Elger *et al.* 2005; Hamandi and Sander 2006). Response rates for pregabalin dosed at 600 mg/day were similar to those reported in other trials of antiepileptic drugs in refractory epilepsy. The study by Elger *et al.* (2005) showed that pregabalin administered in either fixed or flexible dosages was highly effective and generally well tolerated as an add-on therapy for partial seizures with or without secondary generalization.

Nonepilepsy Neurological Conditions

Four placebo-controlled studies have evaluated the efficacy of pregabalin in neuropathic pain (Dworkin *et al.* 2003; Freynhagen *et al.* 2005; Sabatowski *et al.* 2004; van Seventer *et al.* 2006). The first (Dworkin *et al.* 2003) was an 8-week parallel-group, double-blind, placebo-controlled, randomized multicenter trial, in which patients with postherpetic neuralgia were randomly assigned to either pregabalin 600 mg/day (300 mg/day if they had reduced creatinine clearance) or placebo. At the study endpoint, a significantly greater decrease in mean pain scores was found for patients treated with pregabalin compared with those receiving placebo; this improvement was identified as early as day 2 and was maintained throughout the 8 weeks of double-blind treatment. In the second study (Freynhagen *et al.* 2005), patients with chronic postherpetic neuralgia or diabetic peripheral neuropathy were randomly assigned to placebo, flexible-dosage pregabalin titrated upward to a maximum of 600 mg/day, or fixed-dosage pregabalin at 300 mg/day for the first week followed by 600 mg/day for the remaining 11 weeks. Both flexible-and fixed-dosage pregabalin significantly reduced endpoint mean pain scores and were significantly superior to placebo in improving pain-related sleep interference.

In the third study, van Seventer *et al.* (2006) evaluated pregabalin (150, 300, or 600 mg bid) versus placebo in 370 patients with postherpetic neuralgia. At the endpoint, significantly greater dose-proportional pain relief was evident among patients who received pregabalin versus placebo. Sleep interference in all pregabalin groups was

significantly improved at endpoint. Similar results were obtained in the fourth study (Sabatowski *et al.* 2004), which reported improvement in sleep and mood disturbance in patients treated with pregabalin. In total, these four studies showed benefit in pain reduction, sleep improvement, and mood associated with pregabalin treatment. The most common side effects were dizziness, peripheral edema, weight gain, and somnolence.

Freeman *et al.* (2008) conducted a pooled analysis of data from seven published randomized placebo-controlled trials encompassing 400 patients with diabetic peripheral neuropathy. The primary outcome measure was change from baseline to endpoint in mean pain score from patients' daily pain diaries. With three-times-daily administration, all pregabalin dosages (150, 300, and 600 mg/day) produced significantly greater reductions in pain and pain-related sleep interference compared with placebo. With twice-daily administration, only the 600-mg/day dosage showed efficacy. Pregabalin's pain-reducing and sleep-improving properties appeared to be positively correlated with dosage, with the greatest effect observed in patients treated with 600 mg/day.

Fibromyalgia

Pregabalin was the first medication to receive an FDA indication for the treatment of fibromyalgia. Fibromyalgia is a common chronic pain disorder characterized by widespread diffuse musculoskeletal pain and tenderness frequently accompanied by significant psychiatric comorbidity, including fatigue, sleep disturbance, and mood and anxiety disorders. Classifications of disease severity for fibromyalgia have been published by the American College of Rheumatology (Wolfe *et al.* 1990). The prevalence of fibromyalgia in the U.S. population is estimated at 2%, with higher rates in adult women than in men (Arnold *et al.* 2007).

Three placebo-controlled studies--two focused on acute treatment (Crofford *et al.* 2005; Mease *et al.* 2008) and one on relapse prevention (Crofford *et al.* 2008)--evaluated pregabalin's efficacy in the treatment of patients with fibromyalgia. In the first study, an 8-week double-blind, randomized, placebo-controlled investigation of pregabalin (150, 300, and 450 mg/day) versus placebo, the 450 mg/day dosage was associated with significantly greater reductions in the average severity of pain compared with placebo (Crofford *et al.* 2005). Sleep improvement was noted at both the 300-and 450-mg daily dosages. Dizziness and somnolence were the most frequent adverse events. In recognition of the large overlap of psychiatric comorbidity in fibromyalgia, Arnold *et al.* (2007) conducted a post hoc analysis of the Crofford *et al.* (2005) study to assess symptoms of anxiety and depression and their impact on pregabalin treatment. Of 529 patients who had enrolled in pregabalin treatment for fibromyalgia, significantly more endorsed anxiety symptoms (71%) than depressive symptoms (56%). Improvement in pain symptoms with pregabalin versus placebo did not depend on baseline anxiety or depression; in fact, 75% of the pain reduction was not explained by improvements in mood and/or anxiety.

In the second study, 748 patients with fibromyalgia a 13-week double-blind, placebo-controlled multicenter trial were randomly assigned to either placebo or pregabalin at dosages of 300, 450, or 600 mg/day (dosed twice daily) (Mease *et al.* 2008). The primary outcome measure was symptomatic relief of pain associated with fibromyalgia, as measured by a mean pain score from an 11-point numeric rating scale

(0 = no pain; 10 = worst possible pain) from patients' daily diaries. Patients in all pregabalin groups showed statistically significant improvement in endpoint mean pain scores as well as in sleep.

In the third study, pregabalin was evaluated in nearly 600 patients with fibromyalgia in the Fibromyalgia Relapse Evaluation and Efficacy for Durability of Meaningful Relief trial (Crofford *et al.* 2008). This study included an initial 6-week open-label phase followed by 26 weeks of double-blind treatment with continued pregabalin or blind substitution with placebo. The primary outcome measure was time to loss of therapeutic response, defined as a less than 30% reduction in pain or worsening of symptoms of fibromyalgia. Time to loss of therapeutic response was significantly greater for the pregabalin group than for the placebo group, with Kaplan-Meier estimates of time to event showing that half of the placebo group had relapsed by day 19, whereas half of the pregabalin group had still not lost response by trial end.

Finally, pregabalin was investigated as an adjunct to antidepressant medication in patients with fibromyalgia and comorbid depression (Arnold *et al.* 2015). In this randomized, placebo-controlled, double-blind crossover study, patients receiving stable treatment with selective serotonin reuptake inhibitor or serotonin-norepinephrine reuptake inhibitor antidepressants were randomly assigned to adjunctive pregabalin or placebo for 6 weeks, followed by a 2-week taper/washout phase and a crossover to the opposite adjunctive condition for another 6 weeks. Mean scores on measures of pain, anxiety, depression, and fibromyalgia impact all showed significantly greater improvement with adjunctive pregabalin compared with placebo.

Anxiety Disorders

Generalized anxiety disorder. Findings from four placebo-controlled studies contributed to the approval of pregabalin in Europe for generalized anxiety disorder (Montgomery *et al.* 2006; Pande *et al.* 2003; Pohl *et al.* 2005; Rickels *et al.* 2005). In the first study (Pande *et al.* 2003), 276 patients with generalized anxiety disorder were randomly assigned to pregabalin 150 or 600 mg/day, lorazepam 6 mg/day, or placebo. The 6-week trial included a 1-week placebo lead-in, 4 weeks of blind treatment, and a 1-week taper. The primary efficacy outcome measure was the endpoint Hamilton Anxiety Scale (Ham-A) score. The mean decrease in Ham-A total score from baseline to endpoint in all three active-treatment groups (pregabalin 150 or 600 mg/day and lorazepam 6 mg/day) was significantly greater than the decrease in the placebo group. Percentages of subjects who met a secondary outcome measure--reduction of 50% or greater in Ham-A score--were significantly higher in the pregabalin 600-mg/day group (46%) and the lorazepam group (61%) than in the placebo group (27%). There were no significant differences in response rates by either definition between patients receiving pregabalin 150 mg/day and those receiving placebo.

In the second study, Pohl *et al.* (2005) evaluated twice-daily versus three-times-daily dosing of pregabalin in a 6-week double-blind, placebo-controlled trial. In this study, 250 patients with generalized anxiety disorder were randomly assigned to pregabalin (100 mg bid, 200 mg bid, or 150 mg tid) or placebo. Mean improvement in Ham-A total score was significantly greater with pregabalin at all three dosages than with placebo. Pairwise comparisons of twice-daily versus three-times-daily dosing showed no significant differences in outcome. All three pregabalin groups showed significantly greater improvement compared with placebo at endpoint.

In the third study, which had a 4-week design, Rickels *et al.* (2005) randomly assigned 454 patients with generalized anxiety disorder to receive pregabalin (300, 450, or 600 mg/day), alprazolam (1.5 mg/day), or placebo. The primary outcome measure was change in total Ham-A score from baseline to endpoint. Compared with the placebo group, all treatment groups showed significantly greater reductions in mean Ham-A total score at last-observation-carried-forward analysis. A significantly greater proportion of patients in the pregabalin (all dosages) and alprazolam groups met the endpoint response criterion of a 50% or greater reduction in Ham-A total score than in the placebo group. The response rate for the group receiving pregabalin 300 mg/day (61%) was significantly higher than that for the alprazolam group (43%).

In the only pregabalin study with an active antidepressant comparator to date, Montgomery *et al.* (2006) randomly assigned 421 patients with generalized anxiety disorder to 6 weeks of double-blind treatment with pregabalin (400 or 600 mg/day), venlafaxine (75 mg/day), or placebo. The primary outcome measure was change in Ham-A total score from baseline to last-observation-carried-forward analysis. Pregabalin (both dosages) and venlafaxine produced significantly greater improvement in Ham-A total score than did placebo. Patients receiving pregabalin 400 mg/day experienced significantly greater improvement in all primary and secondary outcome measures compared with those receiving placebo. Rates of discontinuation associated with adverse events were highest in the venlafaxine group (20.4%), followed by the pregabalin 600 mg/day (13.6%), pregabalin 400 mg/day (6.2%), and placebo (9.9%) groups.

Other trials have followed in the wake of these earlier studies. A meta-analysis of seven trials pointed to pregabalin's greater efficacy versus placebo in generalized anxiety disorder, although the effect sizes were relatively small (approximately 0.35 for psychic anxiety symptoms) (Boschen 2011; also see Generoso *et al.* 2017). Pregabalin has also been reported to be an effective adjunctive treatment for patients whose generalized anxiety disorder symptoms are nonresponsive to selective serotonin reuptake inhibitor or serotonin-norepinephrine reuptake inhibitor therapy (Rickels *et al.* 2012). However, a recent add-on study in patients with generalized anxiety disorder or major depressive disorder whose symptoms had not responded to escitalopram failed to show statistically significantly greater benefit with pregabalin compared with placebo (Fountoulakis *et al.* 2019).

Social anxiety disorder. In a study by Pande *et al.* (2004), 135 patients with social anxiety disorder were randomly assigned to 10 weeks of double-blind treatment with a low or high pregabalin dosage (150 vs 600 mg/day) or placebo. The primary outcome measure was change in LSAS total score from baseline to endpoint. Patients randomly assigned to pregabalin 600 mg/day showed significantly greater decreases in LSAS total score compared with those receiving placebo. Significant differences between high-dosage pregabalin and placebo were also noted on several secondary measures, including the LSAS subscales Total Fear, Avoidance, Social Fear, and Social Avoidance. Low-dosage pregabalin (150 mg/day) was not significantly better than placebo. Somnolence and dizziness were the most frequently reported adverse events. In a study in 329 patients with social anxiety disorder, pregabalin 600 mg/day (but not 300 or 450 mg/day) separated from placebo (Feltner *et al.* 2011), a finding consistent with the dosage recommendation of 600 mg/day for efficacy in this disorder. Finally, a long-term study in 153 patients who had responded to an initial course

of pregabalin therapy indicated that 450 mg/day was effective as a maintenance treatment in social anxiety disorder (Greist *et al.* 2011).

Substance-Related Disorders

As noted previously, pregabalin has no hepatic metabolism and is excreted essentially unchanged in the urine. This pharmacokinetic profile is ideal for patients who abuse alcohol or are alcohol dependent and have elevated transaminases but need safe, efficacious treatment for symptoms of alcohol withdrawal. Pregabalin's anticonvulsant, analgesic, and anxiolytic properties and potential utility in alcohol-related disorders were examined in a preclinical study using a mouse model of alcohol dependence (Becker *et al.* 2006). Controlled clinical studies of pregabalin in alcohol-dependent patients are needed.

A study in patients with generalized anxiety disorder indicated that pregabalin was efficacious in facilitating discontinuation of long-term benzodiazepine therapy (Hadley *et al.* 2012).

Side Effects and Toxicology

In general, the side effects commonly occurring with pregabalin treatment have been mild and not associated with a severity sufficient to warrant drug discontinuation. The most frequently reported symptoms have been dizziness, sedation, dry mouth, edema, blurred vision, weight gain, and concentration difficulty. In controlled clinical trials with pregabalin, significant weight gain ([?] 7% over baseline) was observed in 9% of patients treated with pregabalin compared with 2% of patients receiving placebo. Pregabalin treatment does not seem to be associated with significant changes in heart rate, blood pressure, respiration, or electrocardiogram measures. Peripheral edema has occurred in a small percentage of patients, but only in rare circumstances has it been identified as severe.

Pregabalin is a U.S. Drug Enforcement Agency (DEA) schedule V drug. Available preclinical and clinical data suggest that pregabalin has very low abuse liability and is unlikely to produce significant physical dependence. There have been postmarketing reports of angioedema and hypersensitivity in patients treated with pregabalin (Pfizer 2018). As noted earlier for gabapentin, pregabalin has been reported to be subject to abuse, particularly in substance abuse settings and among individuals with opioid dependence (Evoy *et al.* 2017).

Drug-Drug Interactions

Pregabalin does not induce or inhibit CYP enzymes, nor do CYP enzyme inhibitors alter its pharmacokinetics as a consequence. Therefore, hepatic and CYP drug-drug interactions are not relevant when pregabalin is part of a complex polypharmacotherapy regimen. Because of the drug's renal elimination, dosage adjustment is required for patients with renal impairment. To date, no pharmacokinetic drug-drug interactions have been identified. There is some literature to suggest that there can be an additive cognitive impairment when pregabalin is taken in conjunction with oxycodone and that pregabalin may potentiate the effects of lorazepam and alcohol (Pfizer 2018).

Summary for Pregabalin

Controlled studies of pregabalin clearly indicate its efficacy in complex partial epilepsy, postherpetic neuropathy, diabetic neuropathy, fibromyalgia, generalized anxiety disorder, and social anxiety disorder. Like gabapentin, pregabalin has a favorable pharmacokinetic profile, with particular advantages in patients with compromised hepatic function. Its minimal drug-drug interactions, low risk of toxicity, and favorable side-effect profile make pregabalin a useful addition to the pharmacopoeia.

Conclusion

There is increasing interest in the use of gabapentoid drugs in mood and anxiety disorders. Both gabapentin and pregabalin have demonstrated efficacy for pain, fibromyalgia, and specific anxiety disorders. Gabapentin also seems to have potential use in cannabis and alcohol use disorders. To date, the use of gabapentin and pregabalin in the treatment of bipolar disorder has not been demonstrated in controlled clinical trials.

CHAPTER 41

Lamotrigine

Keming Gao, M.D., Ph.D.
Joseph R. Calabrese, M.D.

History and Discovery

During the clinical development of lamotrigine as a treatment for intractable seizures, improved mood in lamotrigine-treated patients was anecdotally reported. Smith *et al.* (1993) found that when lamotrigine was added to an existing antiepileptic drug regimen for 81 patients with epilepsy, they reported significantly higher levels of happiness and perceived internal locus of control. The lack of correlation between perceived happiness and changes in seizure frequency or severity suggested that lamotrigine may affect mood independent of its antiepileptic effect.

Structure-Activity Relations and Pharmacological Profile

Lamotrigine (3,5-diamino-6-[2,3-dichlorophenyl]-1,2,4-triazine, $C_9H_7Cl_2N_5$) (Figure 41-1) is an antiepileptic drug of the phenyltriazine class that is chemically unrelated to carbamazepine, valproic acid, phenobarbital, phenytoin, and other established antiepileptic drugs. Lamotrigine seemingly does not inhibit the reuptake of monoamines but has weak inhibitory effects at serotonin$_3$ (5-HT$_3$) receptors. Lamotrigine does not have high binding affinity to adrenergic, dopaminergic, GABAergic, histaminergic, kappa opioid, sigma, or muscarinic acetylcholine receptors, but it inhibits use-dependent sodium channels, allowing continued normal depolarizations while suppressing paroxysmal burst firing encountered in seizures and hypoxic insult.

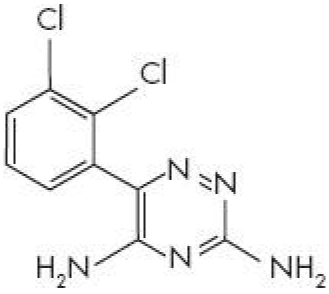

FIGURE 41-1. Chemical structure of lamotrigine.

Pharmacokinetics and Disposition

Oral lamotrigine is rapidly absorbed with negligible first-pass metabolism, and its absorption is not affected by food. Peak plasma concentrations are reached in approximately 1.4-4.8 hours. Lamotrigine's half-life is approximately 25 hours but can be highly variable. For example, in drug-naive adults, the half-life of lamotrigine is 24.1-35 hours (Garnett 1997). In patients receiving other antiepileptic drugs, the half-life can vary from 12.6 to 58 hours (GlaxoSmithKline 2023).Lamotrigine is approximately 55% bound to plasma proteins and is unlikely to significantly interact with drugs that are highly protein bound. Metabolism is primarily achieved by competitive glucuronic acid conjugation. The pharmacokinetics of lamotrigine are linear within a dosage range of 100-700 mg/day (Leach *et al.* 1995). Clearance is reduced in renal insufficiency and hepatic disease.

Estradiol upregulates uridine diphosphate-glucuronosyltransferase UGT1A4 (Chen *et al.* 2009), an enzyme that catalyzes 90% of lamotrigine conjugation (Fotopoulou *et al.* 2009). The rate of lamotrigine clearance increases during each trimester of pregnancy, reaching a peak of 330% of baseline clearance by gestational age 32 weeks (Pennell *et al.* 2004). Active monitoring of lamotrigine levels during pregnancy is recommended in the neurology setting (Harden *et al.* 2009), but the usefulness of monitoring lamotrigine levels during psychiatric treatment during pregnancy remains unclear (Deligiannidis *et al.* 2014). However, if lamotrigine dosing has been increased throughout pregnancy, then the dosage should be decreased immediately after delivery by 20%-25% to prevent toxicity (Clark *et al.* 2013).

Mechanism of Action

Lamotrigine's mechanism of action remains unknown, although its ability to block sodium and N-type calcium channels (Grunze *et al.* 1998) and inhibit glutamate release is believed to be key to its antiepileptic and mood-stabilizing effects. Presynaptic inhibition of voltage-and use-sensitive sodium channels, calcium channels, and potassium channels is believed to result in decreased release of glutamate. Meanwhile, lamotrigine may reduce postsynaptic glutamatergic transmission through suppression of postsynaptic a-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (Lee *et al.* 2008). Lamotrigine may also increase brain levels of *N*-acetylaspartate to enhance neuronal viability and prevent cell death from excessive glutamatergic tone (Croarkin *et al.* 2015).

Indications and Efficacy

In 2003, the FDA approved lamotrigine for use in the maintenance treatment of bipolar I disorder. Lamotrigine is also indicated for adjunctive antiepileptic therapy in adults and pediatric patients (age [?] 2 years) with partial seizures, generalized seizures secondary to Lennox-Gastaut syndrome, or primary and generalized tonic-clonic seizures as well as for monotherapy in patients (age [?] 16 years) with partial seizures (GlaxoSmithKline 2023).

Maintenance Therapy in Bipolar I Disorder

Two large randomized, double-blind, placebo-controlled multicenter investigations led to FDA approval of lamotrigine as a maintenance treatment for bipolar I disorder (Bowden *et al.* 2003; Calabrese *et al.* 2003). Both studies used a relapse-prevention design, in which patients with bipolar I disorder were treated with lamotrigine, and their symptoms improved and stabilized before random assignment to lamotrigine, lithium, or placebo (Gao *et al.* 2009, 2016).

One study enrolled patients who were or had recently been in a manic, hypomanic, or mixed state (Bowden *et al.* 2003). Another study enrolled patients who were or had recently been depressed (Calabrese *et al.* 2003). In the initial analysis and a post hoc analysis (Goodwin *et al.* 2004), both lamotrigine and lithium were significantly superior to placebo in delaying the time to intervention for any mood episode regardless of index episodes. Lamotrigine but not lithium was significantly superior to placebo in prolonging the time to a depressive episode; in addition, lithium but not lamotrigine was significantly superior to placebo in prolonging the time to a manic, hypomanic, or mixed episode. However, lithium and lamotrigine had similar effectiveness in preventing any mood, manic or hypomanic, or depressive relapses in a clinical setting (Licht *et al.* 2010). The efficacy of lamotrigine in delaying depressive relapse was also observed in a relapse-prevention study of combination aripiprazole-lamotrigine versus placebo plus lamotrigine (Carlson *et al.* 2012; Gao *et al.* 2016).

Monotherapy or Adjunctive Therapy in Bipolar Depression

Monotherapy in Bipolar Depression

In a previous study, lamotrigine 200 mg/day showed significant antidepressant efficacy in bipolar depression compared with placebo (Calabrese *et al.* 1999). However, the subsequent four randomized placebo-controlled trials failed to show significant differences between lamotrigine monotherapy and placebo (Calabrese *et al.* 2008). In a pooled analysis of

1,072 participants in all five randomized controlled trials, Geddes *et al.* (2009) found that a significantly greater proportion of patients receiving lamotrigine achieved response status compared with placebo. The advantage of lamotrigine over placebo was greater for patients with more severe depression. In another study, a beneficial effect of lamotrigine in bipolar depression was largely limited to depressive cognitions and psychomotor disturbance (Mitchell *et al.* 2013).

The efficacy of lamotrigine in bipolar depression was further demonstrated in a large randomized, double-blind, head-to-head 7-week study examining combination olanzapine-fluoxetine versus lamotrigine (Brown *et al.* 2006). Overall response and remission rates with lamotrigine were comparable to those with olanzapine-fluoxetine. The insignificant difference in response, remission, or relapse between lamotrigine and olanzapine-fluoxetine continued during the 25-week extension, although olanzapine-fluoxetine was superior to lamotrigine in reducing depressive and manic symptoms (Brown *et al.* 2009). The incidence of suicidal and self-injurious behavior was significantly higher among patients receiving lamotrigine compared with those receiving olanzapine-fluoxetine (3.4% vs. 0.5%). The efficacy of lamotrigine for bipolar II depression was also comparable to that of lithium (Suppes *et al.* 2008).

Adjunctive Therapy in Bipolar Disorder

Lamotrigine added to lithium or valproate. Among patients for whom lithium (0.6-1.2 mmol/L) was ineffective for bipolar I or II disorder, lamotrigine added to lithium for at least 2 weeks was significantly more effective in reducing depressive symptoms than placebo added to lithium (van der Loos *et al.* 2009). For nonresponders in both groups, adding paroxetine for another 8 weeks did not change depressive symptoms significantly (van der Loos *et al.* 2010). Responders taking lamotrigine during two phases of treatment had a significantly longer time to relapse or recurrence during the 68-week follow-up period than those receiving placebo (van der Loos *et al.* 2011).

The addition of lamotrigine or quetiapine to lithium or valproate had similar efficacy in acute bipolar depression, but adjunctive therapy was more effective than lithium or valproate monotherapy, with significantly longer survival times (hazard ratio = 6.8) (Gao *et al.* 2020). A temporary increase in depression with monotherapy, even with mild severity for just 1 week, was associated with a significantly increased risk for dropout in the groups in which lamotrigine or quetiapine was not added.

Combination quetiapine-lamotrigine. The combination of quetiapine and lamotrigine was superior to quetiapine alone in reducing depressive symptoms among patients with bipolar I or II depression (Geddes *et al.* 2016). The insignificant difference at 12-week assessment was attributable to an interaction between lamotrigine and folic acid--that is, folic acid reduced the antidepressant efficacy of lamotrigine. However, folic acid alone was not superior to placebo in reducing depressive symptoms, suggesting that folic acid should be avoided when lamotrigine is used as an antidepressant.

Additional Uses

Bipolar Disorder With Rapid Cycling

In several small studies, investigators did not find significant efficacy of lamotrigine over placebo in acute treatment of patients with bipolar disorder with rapid cycling (Kemp *et al.* 2012; Wang *et al.* 2010). In an earlier study, there was no significant difference between lamotrigine and placebo in time to mood relapse in bipolar disorder with rapid cycling (Calabrese *et al.* 2000). However, overall survival time in the study was significantly different between the treatment groups in favor of lamotrigine. For patients with bipolar II disorder, lamotrigine was significantly superior to placebo, with a median survival time of 17 versus 7 weeks.

Bipolar Disorder With Substance Use Disorder

Lamotrigine may be useful in both improving mood and reducing substance use for patients with bipolar disorder and a substance use disorder, although its efficacy in reducing substance use seems to be limited (Brown *et al.* 2003, 2012; Rubio *et al.* 2006). Lamotrigine and valproate may be the preferred agents for comorbid substance use and bipolar disorder (Coles *et al.* 2019).

Children, Adolescents, and Elderly Individuals With Bipolar Disorder

To date, there are no acute randomized placebo-controlled trials of lamotrigine in the treatment of pediatric bipolar disorder. However, open-label studies showed that lamotrigine monotherapy or adjunctive therapy was effective in reducing depressive and manic symptoms in patients with pediatric bipolar disorder (Biederman *et al.* 2010; Chang *et al.* 2006). Open-label and blind data also suggested that lamotrigine monotherapy or adjunctive therapy was efficacious in maintenance treatment of pediatric bipolar disorder (Findling *et al.* 2015; Pavuluri *et al.* 2009). The maintenance efficacy of lamotrigine in 13-to 17-year-olds was more robust than that in 10-to 12-year-olds, suggesting that lamotrigine may be more useful in a subset of older adolescents (Findling *et al.* 2015). Lamotrigine was efficacious and well tolerated in elderly patients with bipolar I or II depression (Sajatovic *et al.* 2011).

Menstrual Cycle-Related Mood Variability in Women With Bipolar Disorder

Because lamotrigine is implicated in the modulation of glutamatergic and potentially GABAergic signaling, this drug has been hypothesized to affect menstrual cycle-related alterations in neurotransmitter activity. Among women with bipolar disorder whose regimens included lamotrigine, less intraindividual variability in mood was evidenced across menstrual cycle phases (Robakis *et al.* 2015). Although the effect was small, it represents preliminary evidence for lamotrigine's potential utility in treating menstrual cycle-entrained mood cyclicity.

Bipolar Mania and Schizophrenia

In early studies in bipolar disorder, lamotrigine failed to separate from placebo in reducing manic symptoms. In two placebo-controlled trials in schizophrenia, lamotrigine used as an adjunct to antipsychotic treatment was not more effective than adjunctive placebo in reducing negative and positive symptoms of schizophrenia (Goff *et al.* 2007); however, in one of the trials, the cognitive composite score improved more with lamotrigine than with placebo. The effect on schizophrenia psychopathology of adding adjunctive lamotrigine to clozapine was not significantly superior to the effect of adding placebo (Zheng *et al.* 2017).

Monotherapy or Adjunctive Therapy for Major Depressive Disorder

Lamotrigine monotherapy for nonrefractory major depressive disorder has not been shown to significantly differ from placebo. In a network meta-analysis, Zhou *et al.* (2015) also did not find significant differences between lamotrigine and placebo adjunctive therapy to antidepressants in major depressive disorder. However, a meta-analysis including all studies of lamotrigine in mood disorders (bipolar depression and major depressive disorder) showed that lamotrigine was significantly superior to placebo in reducing depressive symptoms, but the results in subgroups were less robust (Solmi *et al.* 2016). In a recent meta-analysis including six studies published in Chinese, Goh *et al.* (2019) found that lamotrigine augmentation was effective in reducing depressive symptoms for patients with treatment-resistant major depressive disorder.

Obsessive-Compulsive Disorder and Eating Disorders

Lamotrigine may be used in combination with selective serotonin reuptake inhibitors or monotherapy for OCD (Hirschtritt *et al.* 2017; Zhou *et al.*

2019). However, lamotrigine-induced OCD or obsessive behavior in patients with bipolar disorder has been reported (Kemp *et al.* 2007; Sharma and Doobay 2019). Lamotrigine with dialectical behavior therapy may improve mood symptoms, behavioral dysregulation, and binge-eating behaviors (Trunko *et al.* 2017). However, lamotrigine 236 +- 150 mg/day had efficacy similar to placebo in reducing binge-eating measures, weight, BMI, and other obsessive-compulsive and impulsive symptoms (Guerdjikova *et al.* 2009).

Borderline Personality Disorder

A lack of efficacy for lamotrigine in borderline personality disorder was demonstrated in a large multicenter randomized, double-blind, placebo-controlled trial of 276 patients (Crawford *et al.* 2018). There was no significant difference between lamotrigine ([?] 400 mg/day) and placebo in the treatment of borderline personality disorder after 52 weeks. Costs of direct care were also similar in the two groups. A meta-analysis of two randomized controlled trials with 330 patients also did not demonstrate any significant difference between lamotrigine and placebo for borderline personality disorder (Pahwa *et al.* 2020).

Dosing Recommendations

The recommended dosing schedule for lamotrigine in adults involves initiating therapy with 25 mg/day for the first 14 days and then increasing to 50 mg/day for weeks 3 and 4 of treatment. During week 5 of treatment, lamotrigine can be increased to 100 mg/day, followed by titration to 200 mg/day during weeks 6 and 7. When lamotrigine is used to augment valproate therapy for adult patients, the recommended titration schedule (rate of dosage escalation) is half the rate for individuals not taking valproate (Table 41-1). The dosage escalation rate for lamotrigine used as an adjunct to treatment with an enzyme-inducing antiepileptic drug is double the rate for patients not taking an enzyme-inducing drug (Table 41-2). For patients older than 12 years with epilepsy, the titration schedule should follow the 2023 product labeling for lamotrigine (GlaxoSmithKline 2023; Table 41-3). To date, no published data support improved efficacy for lamotrigine in the treatment of bipolar disorder at dosages greater than 200 mg/day in the absence of an enzyme inducer. In addition, there is no clear association between serum levels of lamotrigine and measures of affective response.

TABLE 41-1. Recommended titration schedule for lamotrigine for patients with bipolar disorder taking valproate

Week	Dosage
Weeks 1 and 2	25 mg every other day
Weeks 3 and 4	25 mg daily
Week 5	50 mg daily
Week 6	100 mg daily
Week 7	100 mg daily

Note. The usual maintenance dosage when lamotrigine is added to valproate is 100 mg/day.
Source. Adapted from GlaxoSmithKline 2023.

TABLE 41-2. Recommended titration schedule for lamotrigine when used as monotherapy and when added to an enzyme-inducing antiepileptic drug regimen[a] (without valproate)

	For patients NOT TAKING an enzyme-inducing antiepileptic drug regimen[a] and not taking valproate	For patients TAKING an enzyme-inducing antiepileptic drug regimen[a] and not taking valproate

[a] Carbamazepine, phenytoin, phenobarbital, primidone, and rifampin have been shown to increase the apparent clearance of lamotrigine.

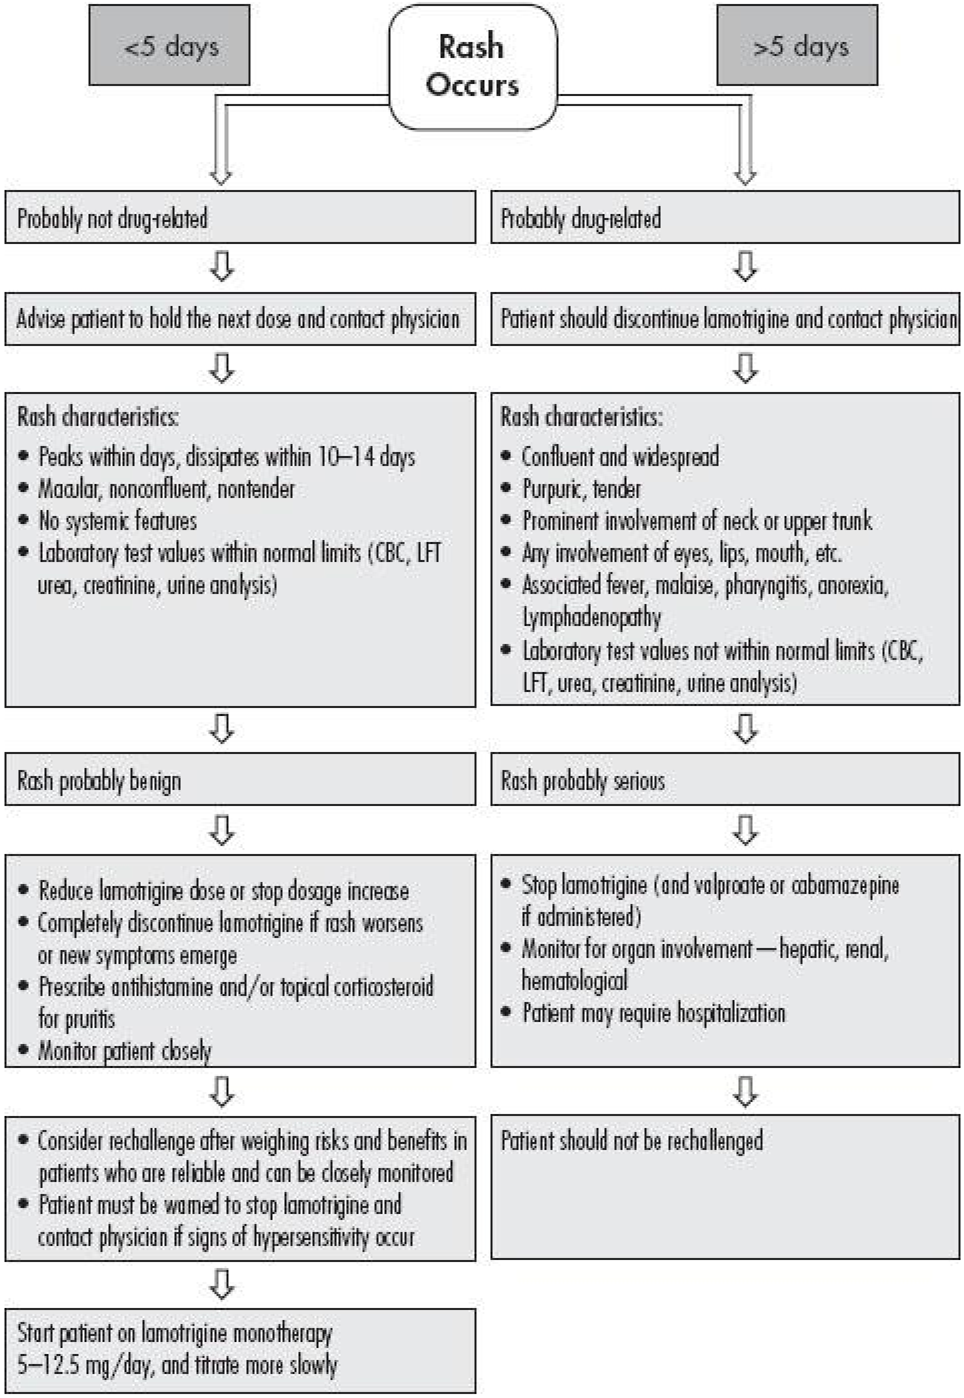
Side Effects and Toxicity

In controlled monotherapy trials of lamotrigine in mood disorders, the drug was associated with headache, nausea, dizziness, and changes in sleep habits (Bowden *et al.* 2004). In randomized trials of lamotrigine in mood disorders, the prevalence of rash did not exceed that of placebo; however, rash is generally recognized as the side effect most likely to significantly complicate clinical use of the drug.

Skin Reactions

The most common lamotrigine-associated rash is an exanthematic maculopapular or morbilliform eruption that is benign. However, a clinically similar eruption may be associated with rarer and more serious systemic hypersensitivity reactions (Guberman *et al.* 1999). Figure 41-2 presents a decision-making algorithm for the management of benign and serious rashes (Calabrese *et al.* 2002). A serious lamotrigine rash is usually confluent with prominent facial and neck involvement. The rash may be tender or have a purpuric or hemorrhagic appearance, or it may be accompanied or preceded by fever, malaise, pharyngitis, anorexia, or lymphadenopathy (Guberman *et al.* 1999). Thus, all patients who develop a rash during the first few months of lamotrigine therapy should be instructed to hold the next dose and immediately seek medical consultation. The greatest risk of rash appears to be during the first 8 weeks of treatment. Nearly all cases of life-threatening rashes caused by lamotrigine have occurred within 2-8 weeks of treatment initiation (GlaxoSmithKline 2023). A rash during the first 5 days of therapy is usually attributable to a nondrug cause. Because immune tolerance to lamotrigine is lost after dosage interruption for more than 1 week, patients should be instructed to resume lamotrigine at the prior initial starting dose and to gradually titrate upward whenever therapy has been interrupted for more than 2 days.



<5 days
Rash Occurs
>5 days
Probably not drug-related
Probably drug-related
Advise patient to hold the next dose and contact physician
Patient should discontinue lamotrigine and contact physician
Rash characteristics:
• Peaks within days, dissipates within 10–14 days
• Macular, nonconfluent, nontender
• No systemic features
• Laboratory test values within normal limits (CBC, LFT urea, creatinine, urine analysis)
Rash characteristics:
• Confluent and widespread
• Purpuric, tender
• Prominent involvement of neck or upper trunk
• Any involvement of eyes, lips, mouth, etc.
• Associated fever, malaise, pharyngitis, anorexia, Lymphadenopathy
• Laboratory test values not within normal limits (CBC, LFT, urea, creatinine, urine analysis)
Rash probably benign
Rash probably serious
• Reduce lamotrigine dose or stop dosage increase
• Completely discontinue lamotrigine if rash worsens or new symptoms emerge
• Prescribe antihistamine and/or topical corticosteroid for pruritis
• Monitor patient closely
• Stop lamotrigine (and valproate or cabamazepine if administered)
• Monitor for organ involvement—hepatic, renal, hematological
• Patient may require hospitalization
• Consider rechallenge after weighing risks and benefits in patients who are reliable and can be closely monitored
• Patient must be warned to stop lamotrigine and contact physician if signs of hypersensitivity occur
Patient should not be rechallenged
Start patient on lamotrigine monotherapy 5–12.5 mg/day, and titrate more slowly

FIGURE 41-2. Clinical management of rash related to lamotrigine treatment.

Note. CBC = complete blood count; LFT = liver function test.

Psychiatry 63:1012-1019, 2002. Copyright 2002, Physicians Postgraduate Press. Used with permission.

In early epilepsy trials, rash led to hospitalization and treatment discontinuation or was diagnosed as Stevens-Johnson syndrome (SJS) in 0.3% of adults taking lamotrigine (Calabrese *et al.* 2002). The annual incidence of serious drug-based skin reactions associated with lamotrigine (e.g., SJS, toxic epidermal necrosis [TEN], and drug rash with eosinophilia and systemic symptoms) was highest in 1993 (4.2%) but steadily declined and had stabilized by 1998 (0.02%). A higher starting dose was significantly associated with an increased risk for severe rash, including TEN and SJS (Wong *et al.* 1999). TEN covering 30% or more of the body surface area was recognized as being serious

and life-threatening. In contrast, SJS rashes covering only 10% or less of the body surface area were considered less serious. However, both TEN and SJS are life-threatening and believed to be caused by impaired clearance of toxic drug metabolites that leads to rash, fever, and skin and mucosal slough.

Since 2013, the starting dosage and the titration rate have been widely recognized as two factors contributing to risk of lamotrigine-induced rash. The risk of rash is heightened by exceeding the recommended initial dosage or the rate of dosage escalation of lamotrigine and by coadministering lamotrigine with valproic acid. The risk is also greater in children younger than age 12 years. To minimize the risk of (life-threatening) rash, lamotrigine should be prescribed as described in Tables 41-1 through 41-3. Clinicians should not deviate from the recommended guidance.

Aseptic Meningitis and Hemophagocytic Lymphohistiocytosis

Rare cases of aseptic meningitis in association with lamotrigine have occurred (Boot 2009; Kilfoyle *et al.* 2005; Lam *et al.* 2010). Clinical manifestations include meningismus, photophobia, headache, vomiting, and fever, which can appear as soon as 1 day or as late as 1.5 months after treatment initiation. In some cases, sudden and severe symptoms of meningitis have occurred within minutes of reintroducing lamotrigine. Most patients recover completely once lamotrigine is discontinued (Moris and Garcia-Monco 1999).

Hemophagocytic lymphohistiocytosis, an immune-related and life-threatening event, has occurred with lamotrigine dosages of 25 mg qod to 250 mg/day (Kim *et al.* 2019). Persistent fever, enlarged liver and lymph nodes, skin rash, yellow skin or eyes, easy bleeding, seizure, unsteady gait, and visual changes can occur. Hemophagocytic lymphohistiocytosis can lead to severe blood cell problems and organ failure. Early recognition and treatment are essential to improve outcomes.

Class IB Antiarrhythmic Activity

The blocking effect of lamotrigine on sodium channels has raised concern regarding its impact on ventricular conduction (Harmer *et al.* 2011). Studies with healthy subjects (Dixon *et al.* 2008) and elderly patients with epilepsy (Saetre *et al.* 2009) did not show a significant effect of lamotrigine on cardiac activity. However, in vitro findings showing lamotrigine's effect on cardiac activity from GlaxoSmithKline (2023), the manufacturer of branded lamotrigine (Lamictal), propelled the FDA to add a cardiac safety warning to the drug label. Patients who have second-or third-degree heart block, ventricular arrhythmia, cardiac disease (e.g., myocardial ischemia, heart failure, structural heart disease, Brugada syndrome), or other sodium channel abnormalities should avoid lamotrigine. Concomitant use of lamotrigine with other sodium channel blockers may increase the risk of arrhythmia.

Weight and Metabolic Neutral Effects

Compared with other agents used to treat bipolar disorder, lamotrigine has a neutral weight and metabolic profile (Brown *et al.* 2009; Sachs *et al.* 2006). A post hoc analysis demonstrated that nonobese individuals taking lamotrigine were unlikely to experience a change in weight. However, obese patients were significantly more likely to lose weight with lamotrigine and to gain weight with lithium (Bowden *et al.* 2006).

Safety in Overdose

In a systematic review of 543 cases of lamotrigine toxicity in overdose, which included data from an earlier case series (Lofton and Klein-Schwartz 2004) of 493 single-substance exposures to lamotrigine, Alabi *et al.* (2016) found that the ingested doses of lamotrigine ranged from 100 mg to 40,000 mg. Although the majority of patients (52.1%) experienced no toxic clinical effects, those who developed symptoms reported effects including drowsiness, vomiting, nausea, ataxia, dizziness, and tachycardia. Rare cases of coma, seizures, heart conduction delay, and respiratory depression have been reported (Alabi *et al.* 2016). Two deaths occurred after ingestion of lamotrigine doses of 4,000 mg and 7,500 mg (Alabi *et al.* 2016).

Use During Pregnancy and Lactation

With regard to teratogenic effects, lamotrigine has been assigned an FDA Pregnancy Category C. At conventional dosages, patients taking lamotrigine may have absolute risks for major congenital malformations similar to those of the general population (Andrade 2018; Veroniki *et al.* 2017a). A prospective observational study from 1999 to 2004 reported that children exposed to lamotrigine in utero had higher IQ scores compared with those exposed to valproate, carbamazepine, or phenytoin (Meador *et al.* 2009). However, a significantly increased risk for autism associated with exposure to lamotrigine monotherapy or lamotrigine-valproate was reported (Veroniki *et al.* 2017b).

Lamotrigine may provide protective effects against mood disorder relapse in pregnancy and seems to be a better choice with less risk of teratogenic effects than other anticonvulsant mood stabilizers and lithium, although its long-term effects on development remain uncertain. If lamotrigine is indicated during pregnancy, a minimum effective dose should be used (especially during the first trimester), even though no dose-dependent effect has been observed with lamotrigine for major congenital malformations and IQ (Andrade 2018). In newborns of mothers receiving lamotrigine, umbilical cord concentrations approached those of maternal serum (Ohman *et al.* 2000). Nursing infants demonstrate plasma lamotrigine concentrations that are approximately 23%-50% of maternal levels.

Drug-Drug Interactions

Lamotrigine is not known to inhibit activity of the cytochrome P450 enzyme CYP2D6. However, the addition of adjunctive lamotrigine to enzyme inducers such as carbamazepine, phenytoin, primidone, and phenobarbital decreases lamotrigine plasma concentrations by approximately 40%-50% (Hahn *et al.* 2004). The inducing effect of oxcarbazepine is approximately half that of carbamazepine (Weintraub *et al.* 2005). Because lamotrigine is nearly exclusively metabolized by glucuronidation, the introduction of adjunctive valproate (an enzyme inhibitor) results in immediate and successful competition for metabolism, with resultant increases in half-life.

Oral contraceptives containing estrogen have the potential to decrease serum concentrations of lamotrigine by up to 64% (Sabers *et al.* 2001, 2003). Use of ethinyl estradiol-containing compounds during long-term lamotrigine treatment may require an increase in lamotrigine to as much as twice the recommended target maintenance dose. Conversely, stopping estrogen-containing oral contraceptives, including during the "pill-free" week, may increase lamotrigine levels to a clinically significant range. Progestins, however, are not associated with a decrease in lamotrigine levels (Reimers *et al.* 2005). Patients with HIV receiving combination ritonavir-atazanavir may require a lamotrigine dosage increase of approximately 50% to maintain unchanged lamotrigine serum concentrations (Birbeck *et al.* 2012).

Lamotrigine Recommendations in Treatment Guidelines

Because of the modest effect sizes of lamotrigine as monotherapy in acute treatment of bipolar depression, recommendations for its use in bipolar disorder vary among national and international treatment guidelines. However, the International Society for Bipolar Disorders has consistently designated lamotrigine as a first-line medication for acute treatment of bipolar depression and for maintenance treatment of bipolar disorders (Yatham *et al.* 2013, 2018). This recommendation is based on lamotrigine's comparable efficacy to other FDA-approved agents such as the olanzapine-fluoxetine combination and quetiapine, as well as on lamotrigine's short-term and long-term benign side-effect profiles.

Conclusion

Although lamotrigine was ineffective in the acute treatment of mania, this drug has demonstrated efficacy and effectiveness in reducing depressive symptoms and preventing mood relapse in bipolar disorder similar to those demonstrated by lithium and some antipsychotics. Lamotrigine's neutral effects on body weight and metabolic function and favorable side-effect profile make it an appealing choice for patients who have comorbid metabolic syndrome or who are unable to tolerate other treatments. At present, lamotrigine remains the only antiepileptic drug mood stabilizer with more established efficacy in the depressed illness phase than in mania or hypomania.

CHAPTER 42

Topiramate

Susan L. McElroy, M.D.
Anna I. Guerdjikova, Ph.D., LISW, CCRC
Francisco Romo-Nava, M.D., Ph.D.

History and Discovery

The FDA approved topiramate for the treatment of epilepsy in 1996, for migraine prevention in 2004, and in combination with phentermine for chronic weight management in 2012. Reports appearing in the late 1990s of the drug having potential beneficial effects in bipolar disorder led Johnson & Johnson Pharmaceutical Research and Development, the discoverer and manufacturer of topiramate, to conduct a large clinical study program of topiramate in the treatment of acute bipolar mania (McElroy and Keck 2004). Controlled trials of the drug in adult patients with manic or mixed symptoms of bipolar disorder failed to demonstrate significant separation between the topiramate-and placebo-treated groups (Kushner *et al.* 2006; Roy Chengappa *et al.* 2006). However, topiramate has been shown in placebo-controlled trials to be efficacious in the treatment of migraine headache and several neuropsychiatric conditions often comorbid with bipolar disorder, including binge-eating disorder, bulimia nervosa, alcohol use disorder, borderline personality disorder, and psychotropic medication-associated weight gain. In addition, mounting evidence suggests that topiramate augmentation of antipsychotic therapy may reduce psychological symptoms in schizophrenia spectrum disorders.

Structure-Activity Relations and Pharmacological Profile

Topiramate (Figure 42-1) has multiple pharmacological properties that may contribute to its anticonvulsant and neuropsychiatric effects (Langtry *et al.* 1997; Rho and Sankar 1999; Rosenfeld *et al.* 1997; Shank *et al.* 2000; White 2002, 2005; White *et al.* 2007). First, topiramate inhibits voltage-gated sodium channels in a voltage-sensitive, use-dependent manner and thus suppresses action potentials associated with sustained repetitive cell firing (Kawasaki *et al.* 1998; Shank *et al.* 2000). Second, topiramate increases brain GABA levels, possibly by activating a site on the $GABA_A$ receptor, thereby enhancing the inhibitory chloride ion influx mediated by the $GABA_A$ receptor and potentiating GABA-evoked currents (Kuzniecky *et al.* 1998; Petroff *et al.* 2001; Simeone *et al.* 2006). Because this action is not blocked by the benzodiazepine antagonist flumazenil, it is thought that topiramate exerts this effect via an interaction with the $GABA_A$ receptor that is not modulated by benzodiazepines (White *et al.* 2000).

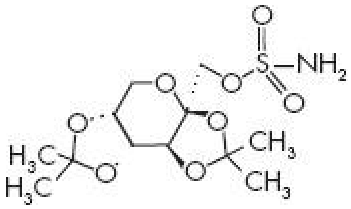

FIGURE 42-1. Chemical structure of topiramate.

Third, topiramate antagonizes glutamate receptors of the a-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)/kainate subtype and may selectively inhibit glutamate receptor 5 kainate receptors (Kaminski *et* al. 2004). Topiramate has essentially no effect on glutamate *N*-methyl-D-aspartate receptors. AMPA/kainate receptors mediate fast excitatory postsynaptic potentials responsible for excitatory neurotransmission; blockade of kainate-evoked currents decreases neuronal excitability.

Fourth, topiramate negatively modulates high-voltage-activated calcium channels (Zhang *et al.* 2000). Of note, Shank *et al.* (2000) proposed that topiramate's combined effects on voltage-activated sodium channels, $GABA_A$ receptors, AMPA/kainate receptors, and high-voltage-activated calcium channels are unique compared with those of other antiepileptic drugs. Indeed, Schiffer *et al.* (2001) found that pretreatment with topiramate inhibited nicotine-induced increases in mesolimbic extracellular dopamine and norepinephrine, but not serotonin. These authors hypothesized that this property was a result of the drug's ability to affect both GABAergic and glutamatergic function.

Fifth, topiramate weakly inhibits certain carbonic anhydrase isoenzymes, including subtypes II and VI. Carbonic anhydrase is essential for the generation of $GABA_A$-mediated depolarizing responses. By inhibiting carbonic anhydrase, topiramate has been shown to reversibly reduce the $GABA_A$-mediated depolarizing responses evoked by either synaptic stimulation or pressure application of GABA (but not to modify $GABA_A$-mediated hyperpolarizing postsynaptic potentials) (Herrero *et al.* 2002).

Finally, topiramate has several other properties. These include an interaction with glycine receptor channels (Mohammadi *et al.* 2005), effects on mitochondrial permeability (Kudin *et al.* 2004), and antikindling properties in some animal models (Wauquier and Zhou 1996).

Formulations

Topiramate is marketed in capsule ("sprinkle capsule"), tablet, extended-release capsule (Janssen Pharmaceuticals 2012), and oral solution (Azurity Pharmaceuticals 2023) formulations. Topiramate's sprinkle capsule formulation is available in the lowest strengths (15 and 25 mg), and may either be swallowed whole or be opened and sprinkled on soft food. It should be noted that the sprinkle capsule and tablet dosage forms are bioequivalent, whereas the tablet is about 80% bioavailable compared with the oral solution. For patients, the Medication Guides issued with many prescribed drugs provide information on the available dosage forms, strengths, and markings (U.S. Food and Drug Administration 2023). These handouts are valuable for educating patients about proper use of drugs and potential side effects and can help reduce the risk of medication errors and severe adverse effects.

Pharmacokinetics and Disposition

Topiramate has a favorable pharmacokinetic profile (Bialer *et al.* 2004; Doose and Streeter 2002; Langtry *et al.* 1997; Rosenfeld 1997; Shank *et al.* 2000). It is rapidly and almost completely absorbed after oral administration, with bioavailability estimated to be approximately 80%. Peak plasma concentrations are reached within 2-4 hours. Plasma concentration increases in proportion to dose over the pharmacologically relevant dose range. Topiramate is minimally protein bound (9%-17%).

Topiramate is minimally metabolized by the liver in the absence of hepatic enzyme-inducing drugs. This agent inhibits cytochrome P450 enzyme (CYP) 2C19 but not other hepatic CYP enzymes. Topiramate is excreted mostly unchanged (approximately 70%) in the urine. The nonrenal (hepatic) clearance of topiramate increases two-to threefold when the drug is administered with hepatic enzyme-inducing drugs such as carbamazepine and phenytoin. Six minor metabolites have been identified (Shank *et al.* 2000).

Topiramate's elimination half-life is 19-25 hours, and steady state is achieved in about 4 days. The pharmacokinetics of topiramate are linear at the dosage range of 100-1,200 mg/day. The pharmacokinetics of topiramate in children are similar to those in adults, except that clearance is 50% higher, resulting in 33% lower plasma concentrations. Moderate or severe renal failure is associated with reduced renal clearance and increased elimination half-life of topiramate. Moderate or severe liver impairment is associated with clinically insignificant increased plasma concentrations of the drug.

Mechanism of Action

Although the mechanism of topiramate's anticonvulsant action is unknown, it has been hypothesized to be attributable to some combination of the drug's multiple pharmacological properties (Rho and Sankar 1999; Shank *et al.* 2000; White 2002, 2005; White *et al.* 2007). For example, topiramate's anticonvulsant profile, as well as its benefits in treating

substance use and eating disorders, has been hypothesized to be attributable to its dual actions on the GABAergic and glutamatergic systems (Johnson *et al.* 2003, 2005; McElroy *et al.* 2003, 2007; Rho and Sankar 1999; Schiffer *et al.* 2001).

Indications and Efficacy

FDA-Approved Indications

Topiramate is FDA approved for the following indications: as initial monotherapy for patients age 10 years or older with partial-onset or primary generalized tonic-clonic seizures; as adjunctive therapy for adults and pediatric patients ages 2-16 years with partial-onset seizures or primary generalized tonic-clonic seizures; and for patients ages 2 years and older with seizures associated with Lennox-Gastaut syndrome (van Passel *et al.* 2006). Topiramate is also approved for the prophylaxis of migraine headache in adults (Brandes 2005; Bussone *et al.* 2006). In 2012, the FDA approved extended-release topiramate in combination with phentermine (marketed under the trade name Qsymia [Vivus 2023]) for long-term weight management as an adjunct to lifestyle modification for people with obesity or overweight (BMI [?] 30 or [?] 27, respectively; calculated as weight in kilograms divided by height in meters squared) who also have at least one weight-related comorbidity (e.g., hypertension or type 2 diabetes mellitus) (Alfaris *et al.* 2015).

Other Indications

Topiramate is not FDA approved for use in the treatment of any psychiatric disorder. Because the drug was widely used off-label in the treatment of bipolar disorder after it came to market (discussed in the next subsection), Johnson & Johnson Pharmaceutical Research and Development conducted a large study program of topiramate in adults with acute bipolar mania. These placebo-controlled studies failed to demonstrate significant benefit of topiramate over placebo on Young Mania Rating Scale (YMRS) scores (Kushner *et al.* 2006; McElroy and Keck 2004). By contrast, findings from randomized placebo-controlled trials suggest that topiramate may be efficacious in major depressive disorder, schizophrenia, binge-eating disorder, bulimia nervosa, alcohol use disorder, other substance use disorders, and psychotropic-induced weight gain. In addition, growing evidence suggests that topiramate may be helpful in movement disorders, including essential tremor (Ferreira *et al.* 2019) and tic disorders (Billnitzer and Jankovic 2020).

Bipolar Disorder

Five randomized placebo-controlled studies have shown that topiramate monotherapy is not efficacious in the short-term treatment of acute manic or mixed episodes in adults with bipolar I disorder (Kushner *et al.* 2006; McElroy and Keck 2004). All five studies used week 3 as the primary endpoint; in addition, three studies had a week 12 secondary endpoint, two studies had lithium comparator groups, and all trials measured weight as a secondary outcome. In each trial, the primary efficacy outcome--the change in YMRS score from baseline to week 3--failed to show a statistically significant separation between topiramate and placebo. There was also no drug-versus-placebo separation in the three trials with week 12 data. By contrast, in the two trials in which lithium was used, lithium did show statistical superiority to placebo.

Similarly, in the only placebo-controlled study of adjunctive topiramate in bipolar disorder to date, 287 outpatients experiencing a manic or mixed episode according to DSM-IV criteria (American Psychiatric Association 1994) and having a baseline YMRS score of 18 or greater while taking therapeutic levels of valproate or lithium showed similar reductions (40%) from baseline YMRS scores for both topiramate and placebo after 12 weeks (Roy Chengappa *et al.* 2006). In the only placebo-controlled study of topiramate in pediatric bipolar I disorder to date, 56 children and adolescents (ages 6-17 years) experiencing a manic or mixed episode were randomly assigned to topiramate monotherapy or placebo for 4 weeks (Delbello *et al.* 2005). The study was initially designed to enroll approximately 230 participants but was prematurely discontinued when results from the adult mania trials were negative. The decrease in mean YMRS score from baseline to final visit using last-observation-carried-forward analysis was not statistically different between treatment groups. However, a post hoc repeated-measures linear regression model of the primary efficacy analysis showed a statistically significant difference in the slopes of the linear mean profiles ($P = 0.003$).

To date, no placebo-controlled study of topiramate has been conducted with patients with acute bipolar depression. Results from an 8-week single-blind comparison trial in which 36 outpatient adults with bipolar depression were randomly assigned to either topiramate (mean dosage [range] = 176 [50-300] mg/day) or sustained-release bupropion (mean dosage = 250 [100-400] mg/day) suggested that topiramate might have antidepressant properties in some patients with bipolar disorder (McIntyre *et al.* 2002). The percentage of patients whose symptoms met a priori response criteria ([?] 50% decrease from baseline in mean total score on the 17-item Hamilton Rating Scale for Depression) was significant for both topiramate (56%) and sustained-release bupropion (59%).

Depressive Disorders

Two randomized placebo-controlled studies of topiramate in patients with major depressive disorder have been conducted. In the first study, 64 female individuals with DSM-IV recurrent major depressive disorder were randomly assigned to topiramate or placebo for 10 weeks (C. Nickel *et al.* 2005a). Topiramate was superior to placebo in reducing depressive and anger symptoms. All subjects tolerated topiramate well, and there were no suicidal events. In the second study, 53 patients with DSM-IV major depressive disorder that was inadequately responsive to an 8-week trial of a selective serotonin reuptake inhibitor (SSRI) were randomly assigned to adjunctive topiramate (100-200 mg/day) or placebo for 8 weeks (Mowla and Kardeh 2011). Topiramate recipients had a 32% mean decrease in Hamilton Rating Scale for Depression scores, whereas placebo recipients had a mean decrease of 5.5%. Topiramate augmentation also produced significantly greater global improvement in depressive symptoms compared with placebo augmentation. Six patients discontinued topiramate because of side effects, which included loss of appetite, gastric disturbance, memory problems, and akathisia. No suicidal events were reported.

Psychotic Disorders

Studies. Seven randomized placebo-controlled studies of topiramate targeting psychopathology in patients with psychotic disorders have been conducted, with mixed

results. Six of these studies involved patients with schizophrenia. The other involved patients with schizoaffective disorder, bipolar type.

Schizophrenia. In the first schizophrenia study, 26 patients with treatment-resistant illness had topiramate (gradually increased to 300 mg/day) or placebo added to their ongoing antipsychotic regimens over two 12-week crossover treatment periods (Tiihonen *et al.* 2005). In the intent-to-treat analysis, topiramate was superior to placebo in reducing general psychopathological symptoms as assessed with the Positive and Negative Syndrome Scale (PANSS), but no significant improvement in positive or negative symptoms was observed.

In the second study, 66 inpatients with schizophrenia who were being treated with risperidone were randomly assigned to augmentation with topiramate (100 or 200 mg/day) or placebo for 12 weeks (Ko *et al.* 2005). Both dosages of topiramate were superior to placebo in reducing psychopathology, as assessed with the Clinical Global Impression Scale Severity of Illness subscale and the Brief Psychiatric Rating Scale.

In the third study, either topiramate ([?] 300 mg/day) or placebo was added to the clozapine regimens of 32 patients with schizophrenia for 56 days (Afshar *et al.* 2009). At day 56, PANSS total scores and scores for all three subscales (negative symptoms, positive symptoms, and general psychopathology) were significantly improved in the topiramate augmentation group compared with the placebo augmentation group.

In the fourth study, 72 drug-naive patients with schizophrenia were randomly assigned to olanzapine plus topiramate 100 mg/day or olanzapine plus placebo for 12 weeks (Narula *et al.* 2010). Compared with the placebo-treated group, the topiramate-treated group showed significantly greater improvement in PANSS total scores ($P = 0.001$) and general psychopathology measures ($P < 0.001$).

In the fifth study, 43 individuals with treatment-resistant schizophrenia who were receiving clozapine were given adjunctive topiramate ([?] 200 mg/day) or placebo for 24 weeks (Muscatello *et al.* 2011). The addition of topiramate was associated with a significant reduction in bizarre behavior as assessed on the Scale for the Assessment of Positive Symptoms ($P < 0.002$); however, no significant improvement in positive, negative, affective, or overall clinical symptomatology was otherwise seen with topiramate.

In the sixth study, either topiramate (200-300 mg/day) or placebo was added to clozapine for 80 hospitalized patients with schizophrenia for 17 weeks (Behdani *et al.* 2011). At endpoint, add-on topiramate was not superior to add-on placebo in reducing positive, negative, or general psychopathological symptoms as assessed by the PANSS.

Schizoaffective disorder. In the schizoaffective disorder study, 48 patients with a diagnosis of DSM-IV schizoaffective disorder, bipolar type, were randomly assigned (2:1, favoring topiramate) to 8 weeks of double-blind adjunctive treatment with topiramate (100-400 mg/day) or placebo

(Roy Chengappa *et al.* 2007). Patients who had achieved at least a 20% decrease from baseline in their PANSS total scores were given the opportunity to continue for an additional 8 weeks of double-blind treatment. Adjunctive topiramate (nearly 275 mg/day) did not show increased efficacy relative to placebo on the PANSS (the primary outcome measure) or on any of the secondary outcome measures.

Meta-analyses Three meta-analyses have included the seven studies just described, and all concluded that topiramate augmentation of antipsychotics may reduce a range of schizophrenia symptoms. In the first meta-analysis, the authors concluded that topiramate as an adjunct to antipsychotics was effective for symptomatic improvement in patients with schizophrenia spectrum disorders (Zheng *et al.* 2016). The authors of the second meta-analysis concluded that topiramate significantly reduced total, positive, negative, and general psychopathology with minimal side effects in patients with schizophrenia spectrum disorder (Correll *et al.* 2016). In the third meta-analysis, the authors concluded that topiramate reduced overall, positive, and negative symptoms (Okuyama *et al.* 2016).

Case reports. There are several case reports of the successful use of topiramate to treat catatonia in patients with chronic psychotic disorders (McDaniel *et al.* 2006). By contrast, there are also reports of the emergence of psychotic symptoms with topiramate treatment (Duan *et al.* 2019; Duggal and Singh 2004; Miller *et al.* 2010).

Eating and Feeding Disorders.

Five randomized placebo-controlled studies involving individuals with bulimia nervosa (two studies) or binge-eating disorder (three studies) demonstrated that topiramate reduces binge eating in both conditions. An additional randomized placebo-controlled trial reported that phentermine-topiramate reduced binge eating in binge-eating disorder and bulimia nervosa (Safer *et al.* 2020). Yet another randomized controlled trial showed that topiramate reduced nocturnal eating in sleep-related eating disorder.

Bulimia nervosa.

The first bulimia nervosa study was a 10-week trial with 69 subjects. Topiramate (median dosage [range] = 100 [25-400] mg/day) was superior to placebo in reducing the frequency of binge and purge days (i.e., days during which at least one binge-eating or purging episode occurred; $P = 0.004$) (Hedges *et al.* 2003; Hoopes *et al.* 2003). Binge-eating/purging remission rates were 32% for topiramate and 6% for placebo (P = not significant). Dropout rates were 34% for topiramate and 47% for placebo. In the second study, subjects with DSM-IV bulimia nervosa received 10 weeks of topiramate (titrated to 250 mg/day in week 6; $n = 30$) or placebo ($n = 30$) (C. Nickel *et al.* 2005b). Topiramate was associated with significant decreases in binge/purge frequency (defined as a > 50% reduction; 37% for topiramate and 3% for placebo), body weight (difference in weight loss between the two groups, 3.8 kg), and scores on all of the 36-Item Short Form Health Survey subscales (all $P < 0.001$).

Binge-eating disorder. In the first controlled study in binge-eating disorder, 61 subjects with DSM-IV binge-eating disorder and obesity received topiramate or placebo for 14 weeks (McElroy *et al.* 2003). Topiramate was significantly superior to placebo in reducing binge-eating frequency as well as global severity of illness, obsessive-compulsive features of binge-eating symptoms, body weight, and BMI. The dropout rate, however, was high: 14 subjects (47%) receiving topiramate and 12 (39%) receiving placebo did not complete the trial.

The second controlled study of topiramate in binge-eating disorder was a multicenter trial in which subjects with DSM-IV binge-eating disorder and at least three binge-eating days per week, a BMI ranging from 30 to 50, and no current psychiatric disorders or substance

abuse were randomly assigned to topiramate or placebo for 16 weeks (McElroy *et al.* 2007). Of 407 subjects enrolled, 13 did not meet the inclusion criteria; 195 topiramate-and 199 placebo-treated subjects were therefore evaluated for efficacy. Topiramate significantly reduced the number of binge-eating days per week, the number of binge-eating episodes per week, weight, and BMI compared with placebo (all $P < 0.001$). The drug also significantly decreased measures of obsessive-compulsive symptoms, impulsivity, hunger, and disability. Fifty-eight percent of topiramate-treated subjects achieved remission, compared with 29% of placebo-treated subjects ($P < 0.001$). Discontinuation rates were 30% in each group; adverse events were the most common reason for topiramate discontinuation (16% vs. 8% for placebo).

The third controlled study of topiramate in binge-eating disorder was another multicenter trial, in which 73 patients with binge-eating disorder and obesity were randomly assigned to 19 sessions of cognitive-behavioral therapy in conjunction with topiramate or placebo for 21 weeks (Claudino *et al.* 2007). Compared with patients given placebo, those given topiramate showed a significantly greater rate of reduction in weight (the primary outcome measure) over the course of treatment ($P < 0.001$). Topiramate recipients also showed a significant weight loss ([?] 6.8 kg) relative to placebo recipients ([?] 0.9 kg). A greater percentage of topiramate-treated patients (31 of 37 [84%]) attained remission of binge eating compared with placebo-treated patients (22 of 36 [61%]; $P = 0.03$). There was no difference in completion rates between groups, although one topiramate recipient withdrew because of an adverse effect.

Phentermine-topiramate for binge-eating disorder and bulimia nervosa.

In a randomized controlled trial, 22 patients with bulimia nervosa ($n = 4$) or binge-eating disorder ($n = 18$) were randomly assigned to 12 weeks of phentermine-topiramate (23 mg per 3.75 mg/day to 92 mg per 15 mg/day) or placebo, followed by a 2-week drug washout and then a 12-week crossover (Safer *et al.* 2020). The number of binge-eating days per month decreased from 16.2 at baseline to 4.2 after phentermine-topiramate versus 13.2 after placebo ($P < 0.0001$). Weight loss was greater with phentermine-topiramate ([?] 5.8 kg) than placebo (+ 0.4 kg). Dropout rates were low (9% for both treatment arms), with few side effects.

Sleep-related eating disorder. In the randomized controlled trial of topiramate in sleep-related eating disorder, 34 patients experiencing three or more sleep-related eating episodes per week were randomly assigned to topiramate ([?] 300 mg/day) or placebo for 13 weeks (Winkelman *et al.* 2020). Topiramate was superior to placebo for reducing sleep-related eating episodes ($P = 0.035$) and was associated with a higher rate of global response (71% for topiramate vs. 27% for placebo; *P* = 0.016). The topiramate group also lost significantly more weight ([?] 8.5 lb vs. + 1.0 lb; *P* = 0.001). However, the drug was not well tolerated, with paresthesia and cognitive dysfunction being the most common side effects. Although it is classified as a parasomnia in DSM-5 (American Psychiatric Association 2013), sleep-related eating disorder shares phenomenological features with night eating syndrome, which DSM-5 lists as an "other specified feeding or eating disorder." Indeed, there are case reports of topiramate being helpful for individuals with night eating syndrome (Kucukgoncu *et al.* 2015).

Other eating and feeding disorders. Currently, there are no randomized controlled studies of topiramate in anorexia nervosa, pica, rumination disorder, or avoidant/restrictive

food intake disorder. However, there are reports of topiramate triggering or worsening anorexia nervosa as well as patients with eating disorders misusing the drug to lose weight (McElroy *et al.* 2008). Conversely, there is one case report of topiramate being helpful for pica (Pena-Salazar and Kazah 2020). Finally, although hyperphagia is not classified as an eating or feeding disorder, one randomized controlled trial showed that topiramate was superior to placebo for reducing hyperphagia in patients with Prader-Willi syndrome (*N* = 62 [Consoli *et al.* 2019]).

Substance-Related and Addictive Disorders

Growing evidence suggests that topiramate may have therapeutic effects in some substance use and addiction disorders, especially alcohol use disorder.

Alcohol use disorder. At least 12 randomized placebo-controlled studies have examined topiramate in alcohol use disorder. In the first study, 150 subjects with DSM-IV alcohol dependence were randomly assigned to topiramate ([?] 300 mg/day) or placebo for 12 weeks (Johnson *et al.* 2003). All participants also received compliance enhancement therapy. At study end, subjects receiving topiramate had significantly fewer drinks per day (*P* = 0.0006), fewer drinks per drinking day (*P* = 0.0009), fewer heavy drinking days (*P* = 0.0003), more days abstinent (*P* = 0.0003), and a log plasma g-glutamyl transferase ratio of 0.07 less ([?] 0.11 to [?] 0.02; *P* = 0.0046) compared with those receiving placebo. Craving was also significantly more improved with topiramate than with placebo.

In the second study, 371 subjects with DSM-IV alcohol dependence were randomly assigned to topiramate ([?] 300 mg/day) or placebo, along with a weekly compliance enhancement intervention, at 16 sites for 14 weeks (Johnson *et al.* 2007). Topiramate was significantly superior to placebo in reducing the percentage of heavy drinking days and other drinking outcomes (e.g., drinks per drinking day), increasing the percentage of days abstinent, and improving the log plasma g-glutamyl transferase ratio (all *P* [?] 0.002).

In the third study, 155 individuals with DSM-IV alcohol dependence who had been detoxified for 1 week were randomly assigned to topiramate ([?] 300 mg/day), naltrexone, or placebo in addition to relapse prevention counseling and encouragement to participate in Alcoholics Anonymous for 12 weeks (Baltieri *et al.* 2008). Topiramate was superior to placebo for time to first relapse, cumulative abstinence duration, weeks of heavy drinking, and percentage of subjects abstinent at 4 and 8 weeks (but not at 12 weeks). There were no significant differences between naltrexone and placebo or between topiramate and naltrexone.

In the fourth study, 63 patients with DSM-IV alcohol dependence were randomly assigned to topiramate or placebo for 12 weeks (Rubio *et al.* 2009). Compared with placebo recipients, topiramate recipients had significantly lower numbers of drinks per drinking day ($P < 0.05$) and of heavy drinking days ($P < 0.001$).

In the fifth study, 170 subjects with comorbid DSM-IV alcohol and cocaine dependence who had attained baseline abstinence were randomly assigned to topiramate (300 mg/day) or placebo in addition to weekly psychotherapy for 13 weeks (Kampman *et al.* 2013). Topiramate was not superior to placebo in reducing alcohol or cocaine use.

In the sixth study, 106 patients with DSM-IV alcohol dependence receiving residential treatment were randomly assigned to topiramate (100-300 mg/day) or placebo for 12 weeks (Likhitsathian *et al.* 2013). No significant differences between the two groups were found in mean percentages of heavy drinking days or time to first day of heavy drinking.

In the seventh study, 138 individuals with heavy drinking (most of whom had symptoms meeting DSM-IV criteria for alcohol dependence) were randomly assigned to topiramate (titrated to 100 mg bid) or placebo for 12 weeks (Kranzler *et al.* 2014). Compared with placebo, topiramate was associated with significantly greater reductions in heavy drinking days and increases in abstinent days ($P = 0.001$ and 0.03, respectively). Moreover, a single-nucleotide polymorphism (rs2832407) in *GRIK1*, which encodes for kainite glutamate receptor subunit GluK1, may have moderated topiramate's effect on heavy drinking. Specifically, topiramate's effect on heavy drinking days was significantly greater than that of placebo only in participants who were rs2832407 C-allele homozygotes.

In the eighth study, 30 veterans with PTSD and a co-occurring alcohol use disorder were randomly assigned to topiramate ([?] 300 mg/day) or placebo for 12 weeks (Batki *et al.* 2014). Compared with placebo, topiramate showed a greater tendency to reduce the primary outcome measure--frequency of drinking days ($P = 0.063$)--but not measures of PTSD symptoms.

In the ninth study, 85 participants with DSM-IV alcohol dependence were randomly assigned to topiramate, zonisamide, levetiracetam, or placebo for 14 weeks (including a 2-week taper period [Knapp *et al.* 2015]). Both topiramate and zonisamide produced significant reductions in drinking behavior. Topiramate and zonisamide both were associated with modest reductions in verbal fluency and working memory, but only topiramate produced a significant increase in mental slowing.

In the tenth study, 12 patients with bipolar disorder and an alcohol use disorder were randomly assigned to topiramate or placebo for 12 weeks (Sylvia *et al.* 2016). Topiramate performed poorly. Only two of five topiramate recipients completed the trial, compared with five of seven placebo recipients. In addition, topiramate did not improve drinking behavior and was poorly tolerated.

In the eleventh study, 32 veterans with alcohol use disorder and concussive symptoms from mild traumatic brain injury were randomly assigned to flexible-dosage topiramate or placebo for 12 weeks (Pennington *et al.* 2020). Alcohol use and concussive symptoms improved in both groups. Among completers, there was a greater reduction of alcohol use among veterans receiving topiramate.

The twelfth study analyzed functional MRI on alcohol cue-elicited brain responses, craving, and heavy drinking from 12 individuals with DSM-5 alcohol use disorder randomly assigned to topiramate (maximum dosage = 200 mg/day) or placebo for 12 weeks (Wetherill *et al.* 2021). Relative to placebo, topiramate produced greater reductions in alcohol cue activation of the left ventral striatum, bilateral orbitofrontal cortex, and medial orbitofrontal cortex as well as in alcohol cue-elicited craving and heavy drinking days.

Cocaine use disorder. At least six randomized placebo-controlled trials have evaluated topiramate in cocaine dependence, with mixed results. In the first study, 40 cocaine-dependent individuals were randomly assigned to topiramate (titrated gradually over 8 weeks to 200 mg/day) or placebo for 13 weeks (Kampman *et al.* 2004). Topiramate-treated subjects were more likely than placebo-treated subjects to be abstinent

from cocaine after week 8 ($P = 0.01$). They were also more likely to achieve 3 weeks of continuous abstinence from cocaine ($P = 0.05$).

In the second study, 81 cocaine-dependent subjects were randomly assigned to topiramate (titrated to 150 mg bid) plus mixed amphetamine salts or placebo for 12 weeks (Mariani *et al.* 2012). The proportion of patients achieving 3 weeks of abstinence was larger for active drug treatment (33.3%) than for placebo (16.7%). Combination treatment may also have been more effective in subjects with a high baseline frequency of cocaine use.

In the third study, 142 patients with DSM-IV cocaine dependence were randomly assigned to topiramate (target maintenance dosage = 300 mg/day) or placebo in combination with cognitive-behavioral therapy for 12 weeks (Johnson *et al.* 2013). Topiramate was more efficacious than placebo at increasing the weekly proportion of nonuse days. It also was associated with significantly more urinary cocaine-free weeks, decreased craving, and improved global functioning.

In the fourth trial, 170 subjects with comorbid DSM-IV cocaine and alcohol dependence were randomly assigned to topiramate 300 mg/day or placebo for 13 weeks (Kampman *et al.* 2013). Topiramate was not superior to placebo for reducing cocaine or alcohol use.

In the fifth study, 171 cocaine-dependent patients undergoing methadone maintenance treatment were randomly assigned to topiramate or placebo in addition to monetary voucher incentives that were either contingent or noncontingent on drug abstinence for 15 weeks (including 8 weeks at a maintenance dosage of 300 mg/day [Umbricht *et al.* 2014]). There were no significant differences between the topiramate and placebo conditions or between the contingent and noncontingent incentive conditions. In addition, there were no topiramate-contingency interactions, and topiramate was associated with cognitive impairment.

In the sixth trial, 127 adults with cocaine use disorder were randomly assigned to the combination of topiramate and mixed amphetamine salts or placebo for 12 weeks (Levin *et al.* 2020). The proportion of patients achieving 3 consecutive weeks of abstinence (the primary outcome) was significantly higher in the active drug group (14%) versus the placebo group (0%; $P = 0.03$). However, 20% of patients in the active drug group were discontinued from study medication.

Methamphetamine use disorder. At least two randomized controlled trials have assessed topiramate in methamphetamine addiction. In the first study, 140 subjects with methamphetamine addiction were randomly assigned to topiramate (target maintenance dosage = 200 mg/day) or placebo for 13 weeks (Elkashef *et al.* 2012). Topiramate did not increase abstinence from methamphetamine over weeks 6-12 of treatment (the primary outcome measure). On secondary outcomes, however, topiramate reduced weekly median urine methamphetamine levels and overall severity of dependence scores ($P = 0.03$ for both).

In the second study, 62 adults with DSM-IV methamphetamine dependence were randomly assigned to topiramate ([?] 200 mg/day) or placebo for 10 weeks (Rezaei *et al.* 2016). At week 6, the topiramate group had a significantly lower proportion of methamphetamine-positive urine test results ($P = 0.01$) compared with the placebo group. Topiramate-treated subjects also had lower scores on the drug use severity and drug need items on the Addiction Severity Index (both $P < 0.001$).

Smoking cessation. At least four randomized placebo-controlled trials have assessed topiramate in smoking cessation. In the first study, topiramate was superior to placebo for abstinence from smoking in 94 subjects with comorbid DSM-IV alcohol dependence (Johnson *et al.* 2005). This 2005 study was a subgroup analysis of the first controlled study of topiramate in alcohol dependence (Johnson *et al.* 2003). In the second study, topiramate was superior to placebo for smoking cessation in male ($n = 38$) but not female ($n = 49$) individuals who had no associated psychopathology (Anthenelli *et al.* 2008). In the third study, which followed a placebo-controlled trial (Baltieri *et al.* 2008) in 155 male outpatients with alcohol dependence (according to ICD-10 criteria [World Health Organization 1992]), a subset of the participants with alcoholism who were smokers ($n = 103$) were randomly assigned to topiramate, naltrexone, or placebo for 12 weeks (Baltieri *et al.* 2009). Whereas naltrexone did not separate from placebo, topiramate was more effective than placebo in reducing the number of cigarettes smoked. In the fourth trial, 129 smoking-and alcohol-abstinent men with alcohol dependence were randomly assigned to topiramate ([?] 200 mg/day) or placebo for 12 weeks (Anthenelli *et al.* 2017). Topiramate had no effect on smoking cessation or alcohol relapse prevention.

Of note, the authors of a systematic review and meta-analysis including these trials concluded that there was not sufficient evidence favoring topiramate over placebo for smoking cessation (Lotfy *et al.* 2020).

Gambling disorder. Topiramate has been evaluated in two randomized placebo-controlled trials in gambling disorder, with mixed results. In the first study, 42 patients with DSM-IV pathological gambling received either topiramate or placebo for 14 weeks (Berlin *et al.* 2013). There were no significant treatment effects of topiramate on the primary outcome (Yale-Brown Obsessive Compulsive Scale [Y-BOCS] adapted for Pathological

Gambling) or any secondary outcome measures. In the second study, 30 participants with gambling disorder were randomly assigned to topiramate or placebo for 12 weeks (de Brito *et al.* 2017). All participants also received a brief cognitive intervention. Topiramate was superior to placebo in reducing gambling craving (*P* = 0.017), time and money spent gambling (*P* = 0.007 and 0.047, respectively), and cognitive distortions related to gambling (*P* = 0.003). Topiramate also improved social adjustment but had no effect on depression or impulsivity.

Posttraumatic Stress Disorder

Topiramate has been evaluated in at least four randomized placebo-controlled studies in PTSD. In the first study, 38 civilian patients with PTSD were randomly assigned to flexible dosages of topiramate (median = 150 mg/day) or placebo for 12 weeks (Tucker *et al.* 2007). No significant difference between topiramate and placebo was found on the primary efficacy measure, change in total Clinician-Administered PTSD Scale (CAPS) score. However, significant reductions in favor of topiramate were observed for the Eight-Item Treatment Outcome Posttraumatic Stress Disorder Scale score, with a decrease in overall severity of 68% for topiramate versus 42% for placebo (*P* = 0.025).

In the second study, 40 male veterans with chronic PTSD, most of whom were receiving antidepressants, were given topiramate ([?] 200 mg/day) or placebo for 7 weeks (Lindley *et al.* 2007). No significant drug-versus-placebo differences were found for the primary outcome measures (i.e., scores on the CAPS, Clinical Global Impression Scale Severity of Illness subscale, or Patient Global Impression of Improvement Scale).

In the third study, 70 civilian patients with PTSD were randomly assigned to receive topiramate (mean dosage = 102.94 mg/day) or placebo for 12 weeks (Yeh *et al.* 2011). Compared with placebo recipients, topiramate recipients showed significantly greater improvement in both re-experiencing and avoidance/numbing symptoms as measured with the

CAPS (*P* = 0.04 and 0.0001, respectively) as well as a significant reduction in CAPS total scores (*P* = 0.0076). Topiramate was generally well tolerated.

In the fourth study, 30 veterans with PTSD and a co-occurring alcohol use disorder were randomly assigned to topiramate ([?] 300 mg/day) or placebo for 12 weeks (Batki *et al.* 2014). Compared with placebo, topiramate showed a greater tendency to reduce drinking frequency (the primary measure; *P* = 0.063) but had no effect on PTSD symptom measures.

At least two meta-analyses including these studies have been published. The first was a meta-analysis of topiramate as monotherapy or adjunctive therapy for PTSD, in which the authors concluded that topiramate produced a small but significant reduction in hyperarousal symptoms (*P* = 0.033) but did not reduce re-experiencing or avoidance symptoms (Varma *et al.* 2018). The second was a network meta-analysis, in which the authors concluded that topiramate was superior to placebo for decreasing PTSD symptoms and should be viewed as an effective treatment option for PTSD (de Moraes Costa *et al.* 2020).

Obsessive-Compulsive Disorder

Four randomized placebo-controlled trials have evaluated adjunctive topiramate in individuals with OCD, with mixed results. In the first study, 41 patients with OCD that had not improved after at least 12 weeks of treatment with an SSRI were randomly assigned to receive topiramate or placebo plus their current OCD regimen for 12 weeks. Recipients of topiramate showed a mean decrease of 32% in Y-BOCS scores, whereas placebo recipients had a decrease of 2.4% (Mowla *et al.* 2010). In the second study, adjunctive topiramate (mean endpoint dosage = 179 mg/day) significantly reduced Y-BOCS Compulsions subscale scores (*P* = 0.014) but not Obsessions subscale scores or total scores for 36 adults with OCD receiving an SSRI (Berlin *et al.* 2011). In the third study, 39 inpatients with OCD and bipolar mania were randomly assigned to have topiramate or placebo added to their current regimen of lithium, olanzapine, and clonazepam for 4 months (Sahraian *et al.* 2014). Y-BOCS scores showed a greater numeric decline for patients receiving placebo than for those receiving topiramate. By contrast, among the 32 completers, there were significantly more responders (defined as a > 34% reduction in Y-BOCS scores) among topiramate recipients than among placebo recipients (53% vs. 12.5%, respectively; $P < 0.01$). However, in the fourth study involving 38 patients with refractory OCD, topiramate (mean dosage = 137.5 mg/day) was not superior to placebo in reducing Y-BOCS scores after 12 weeks of treatment (Afshar *et al.* 2014).

Borderline Personality Disorder

Three randomized placebo-controlled studies conducted by the same group evaluated topiramate in DSM-IV-defined borderline personality disorder (Loew *et al.* 2006; M. K. Nickel *et al.* 2004, 2005a). In the first study, 29 female subjects were randomly assigned (2:1) to topiramate or placebo for 8 weeks (M. K. Nickel *et al.* 2004). The topiramate dosage was increased to 250 mg/day over 6 weeks. At study end, significantly

greater improvement on four subscales of the State-Trait Anger Expression Inventory (state-anger, trait-anger, anger-out, and anger-control) was observed for topiramate-treated participants compared with placebo.

In the second study, 42 male subjects with borderline personality disorder received topiramate or placebo for 8 weeks (M. K. Nickel *et al.* 2005a). As in the study in female subjects, significantly greater improvement on the same four State-Trait Anger Expression Inventory subscales was found for male subjects treated with topiramate compared with placebo.

In the third study, 56 women with borderline personality disorder received topiramate or placebo for 10 weeks (Loew *et al.* 2006). Topiramate was titrated to 200 mg/day over 6 weeks and then held constant. Topiramate was superior to placebo on the somatization, interpersonal sensitivity, anxiety, hostility, phobic anxiety, and Global Severity Index subscales of the Symptom Checklist-90 Revised (all $P < 0.001$), all eight scales of the 36-Item Short Form Health Survey (all $P < 0.01$), and four of eight scales of the Inventory of Interpersonal Problems (all $P < 0.001$). In all three studies, topiramate was well tolerated, and there were no psychotic or suicidal adverse events.

Impulse-Control Disorders

Case reports and open studies suggest that topiramate might be effective in various impulse-control disorders, including intermittent explosive disorder (Yulug *et al.* 2016), kleptomania (Dannon 2003; Kaplan 2007), pyromania (Grant 2006), trichotillomania (Lochner *et al.* 2006), and excoriation (skin-picking) disorder (Jafferany and Osuagwu 2017). However, in a randomized controlled trial in 50 patients with compulsive buying disorder, topiramate was similar to placebo on the primary outcome, the Y-BOCS-Shopping Version (Nicoli de Mattos *et al.* 2020). Nonetheless, topiramate recipients did better than placebo recipients on the Compulsive Buying Follow-Up Scale, a secondary outcome measure.

Although no randomized controlled trial to date has evaluated topiramate in the treatment of intermittent explosive disorder, a systematic review concluded that topiramate might be effective and well tolerated in the treatment of individuals with anger or aggression (Varghese *et al.* 2010). Of note, the studies included in this review evaluated topiramate in the treatment of anger or aggression in individuals with borderline personality disorder, major depressive disorder, or low back pain--conditions with an unclear relationship with intermittent explosive disorder.

Paraphilias

Several case reports suggest that topiramate may be effective in individuals with paraphilias (Wan *et al.* 2019), including fetishism (Shiah *et al.* 2006) and exhibitionism (Bell 2012). There is also one case report of the successful treatment of compulsive sexual behavior with topiramate (Bell 2012).

Psychotropic Medication-Associated Weight Gain

At least five randomized placebo-controlled studies have suggested that topiramate reduces antipsychotic-related weight gain in patients with psychotic or mood disorders. In the first study, 66 inpatients with schizophrenia receiving antipsychotic medication and "carrying excess weight" were randomly assigned to topiramate (100 or 200 mg/day) or placebo for 12 weeks (Ko *et al.* 2005). Body weight, BMI, and waist

and hip circumferences decreased significantly in the group that received topiramate 200 mg/day compared with those that received topiramate 100 mg/day or placebo.

In the second study, 43 women with mood or psychotic disorders who had gained weight while taking olanzapine were given topiramate or placebo for 10 weeks (M. K. Nickel *et al.* 2005b). Weight loss was significantly greater (by 5.6 kg) in the topiramate group. Topiramate-treated subjects also experienced significantly greater improvement in measures of health-related quality of life and psychological impairment.

In a third study, topiramate as an adjunct to lithium or valproate treatment was ineffective for manic symptoms in patients with bipolar I disorder experiencing a manic or mixed episode. However, topiramate was associated with significantly greater reductions in body weight ([?] 2.5 vs. 0.2 kg; $P < 0.001$) and BMI ([?] 0.84 vs. 0.07; $P < 0.001$) versus placebo (Roy Chengappa *et al.* 2006).

In the fourth study, adjunctive topiramate was evaluated for utility in the prevention of olanzapine-related weight gain (Narula *et al.* 2010). In this 12-week trial, 72 patients with schizophrenia were randomly assigned to olanzapine plus topiramate 100 mg or olanzapine plus placebo. Whereas topiramate augmentation was associated with statistically significant weight loss, placebo-augmented olanzapine was associated with significant weight gain ($P = 0.05$ between-group difference). Topiramate augmentation was also associated with significantly greater improvement in several metabolic variables, systolic and diastolic blood pressure, and PANSS General Psychopathology Scale score and total score.

In the fifth study, 68 individuals with bipolar disorder or schizophrenia hospitalized and treated with olanzapine were randomly assigned to one of the following four treatment groups for 12 weeks: placebo or topiramate 50, 100, or 200 mg/day (Talaei *et al.* 2016). Topiramate at all three dosages was superior to placebo in preventing weight gain. There were no differences, however, among the three topiramate dosages.

Of note, several reviews and meta-analyses have evaluated pharmacological interventions for psychotropic-induced weight gain. Most have concluded that topiramate reduced body weight. For example, in a meta-analysis of pharmacological interventions in weight gain management in patients with severe mental illness, which included the topiramate trials just described, the authors concluded that topiramate was efficacious and safe for weight reduction in this patient group (Hiluy *et al.* 2019). In a meta-review of meta-analyses of randomized controlled trials in patients from 15 studies of topiramate in schizophrenia, the authors concluded that topiramate had a "medium" effect size for weight reduction (Vancampfort *et al.* 2019).

Side Effects and Toxicology

The side-effect profile of topiramate may vary with the patient's illness, mood state, and concomitant medications.

Common Side Effects

The most common side effects of topiramate in initial dose-ranging studies in patients with epilepsy when used in combination with other antiepileptic drugs at dosages of 200-1,000 mg/day were related to the CNS. These side effects included dizziness, somnolence, psychomotor slowing, nervousness, paresthesias, ataxia, difficulty with memory, difficulty with concentration or attention, confusion, and speech disorders or related speech problems (Langtry *et al.* 1997; Shorvon 1996). Other side effects were nystagmus, depression, nausea, diplopia, abnormal vision, anorexia, language problems, and tremor. When topiramate was used as monotherapy in patients with epilepsy, the most common side effects were dizziness, anxiety, paresthesias, insomnia, somnolence, myalgia, anorexia, nausea, dyspepsia, and diarrhea. The most common side effects of topiramate in the large registration trials for migraine headache (which used total dosages of 50, 100, and 200 mg/day) were paresthesias, fatigue, memory difficulties, concentration or attention problems, and mood problems (Bussone *et al.* 2006). In the monotherapy trials in adult mania, paresthesias, decreased appetite, dry mouth, and weight loss were more common with topiramate than placebo (Kushner *et al.* 2006). In the obesity trials, events related to the CNS, peripheral nervous system, or psychiatric disorders were most commonly reported (Rosenstock *et al.* 2007). These included paresthesias, fatigue, taste perversion, anorexia, and difficulty with attention, concentration, and/or memory. Overall, paresthesias and cognitive complaints were the most troublesome adverse events (van Passel *et al.* 2006). A meta-analysis suggested that a dose-response relationship exists for dizziness, cognitive impairment, and fatigue (Zaccara *et al.* 2008).

The CNS and gastrointestinal effects of topiramate are usually mild to moderate in severity and often decrease or resolve with time or dosage reduction (Meador *et al.* 2003; Shorvon 1996). In addition, they may be minimized through slow titration of topiramate dosage (Biton *et al.* 2001). However, topiramate may be associated with greater cognitive impairment than some of the other new antiepileptic drugs (Martin *et al.* 1999; Meador *et al.* 2003).

Infrequent Adverse Effects

Infrequent but serious side effects of topiramate include nephrolithiasis, an ocular syndrome of acute myopia with secondary angle-closure glaucoma, oligohydrosis and hyperthermia, and metabolic acidosis (van Passel *et al.* 2006). Mild hypokalemia, which usually is not clinically significant, may also occur in about 10% of topiramate recipients (Dell'Orto *et al.* 2014).

The incidence of topiramate-associated nephrolithiasis has been estimated to be 1.5% (Shorvon 1996). In the epilepsy trials, more than 75% of the patients who developed kidney stones elected to continue treatment with topiramate (Reife *et al.* 2000). Nephrolithiasis is thought to be related to topiramate's inhibition of carbonic anhydrase in the kidney (Welch *et al.* 2006).

The secondary angle-closure glaucoma associated with topiramate is characterized by acute onset of bilateral blurred vision and ocular pain (Fraunfelder 2004; Fraunfelder *et al.* 2004). Ophthalmological findings include bilateral myopia, conjunctival hyperemia, anterior chamber shallowing, and increased intraocular pressure. Most cases have occurred within 1 month of topiramate initiation and fully resolved with drug discontinuation. Peripheral iridectomy and laser iridotomy are not effective. The syndrome has been attributed to sulfamate-induced ciliary body edema.

Oligohydrosis and hyperthermia occurring with topiramate can present as heat stroke or fever, may be related to exercise or high environmental temperature, can be fatal, are probably more common in children than in adults, and are reversible upon drug discontinuation (Karachristianou *et al.* 2013). Topiramate-induced metabolic acidosis is usually asymptomatic and associated with low bicarbonate and, to a lesser degree, increased chloride levels (Dell'Orto *et al.* 2014; Sciegienka *et al.* 2015). Rarely, it presents with Kussmaul breathing or even altered mental status. Topiramate-induced metabolic acidosis may be due to the carbonic anhydrase-inhibiting properties of topiramate, and it is also reversible on drug discontinuation.

Because there were no clinically relevant changes in hepatic, renal, or hematological parameters in the registration trials of topiramate, laboratory monitoring was initially thought to be unnecessary (Reife *et al.* 2000; Sachdeo *et al.* 2002). In addition, no treatment-related changes were noted in physical or neurological examinations (except body weight loss), electrocardiograms, or ophthalmological or audiometric test results. However, because topiramate may cause metabolic acidosis and hypokalemia in some patients, it is now recommended that baseline and periodic serum bicarbonate and potassium levels be measured in patients receiving topiramate (Dell'Orto *et al.* 2014; Sachdeo *et al.* 2002; van Passel *et al.* 2006; Welch *et al.* 2006).

Psychiatric Adverse Events

A growing concern is the psychiatric adverse-event profile of antiepileptic drugs in patients with epilepsy, including the question of whether such drugs cause depression, suicidality, psychosis, or aggression (Dussaule and Bouilleret 2018). Thus, topiramate may be associated with depression in patients with epilepsy, especially during rapid titration (Mula and Sander 2007). There are also isolated reports of topiramate's induction of mood and anxiety symptoms in psychiatric patients (Damsa *et al.* 2006; Duan *et al.* 2019; Klufas and Thompson 2001). Moreover, one obesity study reported eight (6.2%) suicide-related events occurring in topiramate-treated subjects versus none in placebo-treated subjects (Rosenstock *et al.* 2007).

Use in Pregnancy

Topiramate can cause fetal harm when given to pregnant women. Prenatal exposure to topiramate is associated with an increased risk of oral clefts (Alsaad *et al.* 2015; Hunt *et al.* 2008). Topiramate might also contribute to other birth defects, including neural tube defects, when used in combination with other antiepileptics, especially valproate (Vajda *et al.* 2019).

Drug-Drug Interactions

The clearance of topiramate can be increased by coadministration of hepatic enzyme-inducing drugs (Bialer *et al.* 2004; Gidal 2002; Langtry *et al.* 1997; Rosenfeld *et al.* 1997; van Passel *et al.* 2006). Thus, carbamazepine and phenytoin may substantially decrease topiramate levels.

Conversely, topiramate has mild enzyme-inducing properties and may enhance the metabolism of ethinyl estradiol. Available data suggest that this induction is insignificant at topiramate dosages of 200 mg/day or less, but induction becomes dose

dependent at dosages greater than 200 mg/day and occurs to a great extent (Bialer *et al.* 2004). Therefore, women taking combination oral contraceptive agents must be counseled about this potential interaction.

Although there have been reports of topiramate causing increased lithium levels (Abraham and Owen 2004), this effect appears to be only rarely clinically significant (Bialer *et al.* 2004).

Conclusion

In summary, although topiramate does not have regulatory approval for use in the treatment of psychiatric disorders, considerable data suggest that this drug may be helpful for a wide range of psychiatric conditions. Topiramate appears efficacious in binge-eating disorder, bulimia nervosa, psychotropic-associated weight gain, and possibly alcohol use disorders. It might also be efficacious for major depressive disorder, schizophrenia, borderline personality disorder, and PTSD. Data on topiramate's efficacy in cocaine or methamphetamine use disorders, smoking cessation, and OCD have been mixed. Of note, there is no evidence to suggest that topiramate has acute antimanic or long-term mood-stabilizing effects in bipolar disorder. The use of topiramate in psychiatric disorders, however, is limited by its adverse-event profile.

Other Agents

CHAPTER 43

Agents for Neurocognitive Disorders

Gayle Ayers, D.O.

Frank W. Brown, M.D.

Neurocognitive disorder is an umbrella term referring to the heterogeneous and complex disruption of cellular function leading to loss of synaptic plasticity, cell death, gliosis, inflammation, and disruption of the functional networks underlying cognition (Amarapurkar *et al.* 1995; Brun *et al.* 1995; Crews and Masliah 2010; Elahi and Miller 2017; Malik *et al.* 2007; Olajide *et al.* 2021). According to DSM-5 (American Psychiatric Association 2013), a diagnosis of neurocognitive disorder requires a decline from a previous level in at least one area of functioning regarding complex attention, executive function, learning and memory, language, perceptual-motor skills, or social cognition.

Neurocognitive disorders are currently classified based on clinical features, evolution over time, and underlying pathologies primarily categorized according to the accumulation of abnormal protein aggregates in neurons and glia in vulnerable areas of the brain, which can precede clinical manifestation by years (Elahi and Miller 2017; Seeley *et al.* 2009; Sorbi *et al.* 2012). The accuracy of diagnosis is increasingly being improved with the use of imaging, biofluid, and genetic biomarkers, even at times allowing for recognition of the disease process before symptoms are present (Elahi and Miller 2017). Intervention at a stage before irreversible damage occurs would be optimal. Unfortunately, there is currently no clear evidence that any pharmacological intervention can prevent the onset and progression of a major neurocognitive disorder, although several strategies continue to be investigated for possible disease-modifying effects. Aducanumab and lecanemab, the medications most recently approved by the FDA for Alzheimer's disease, lower amyloid b (Ab) plaque levels in the brain. Thus, these are the first FDA-approved drugs to claim an effect on the Alzheimer's disease process.

In this chapter we describe aducanumab, lecanemab, and the other FDA-approved pharmacological approaches proven to provide modest symptomatic relief for certain neurocognitive disorders. In addition, we briefly review other treatments that have been found to provide no benefit and additional future treatments that may hold promise.

Amyloid-Targeted Therapies

Ab plaques and neurofibrillary tangles have been the neuropathological hallmarks of Alzheimer's disease. Tangles are filamentous inclusions of aggregates of misfolded and hyperphosphorylated tau proteins that accumulate intraneuronally. Ab peptides are the product of sequential proteolytic processing of amyloid precursor protein by the enzymes b-secretase and g-secretase. These peptides assemble into insoluble b-fibrillar aggregates that deposit extracellularly in the brain parenchyma and cerebral vasculature (Bloom 2014; Decourt *et al.* 2021; Fowler *et al.* 2006; Love *et al.* 2009; Serrano-Pozo *et al.* 2011). The presence of Ab and tau has been correlated with the progression of Alzheimer's disease, but the mechanism of their toxicity remains controversial and poorly understood. Some argue that Ab is intrinsically toxic, whereas others believe that it seeds the formation of tau tangles and leads to a cascade of pathologically toxic events (Chuang *et al.* 2018; Decourt *et al.* 2021; Guo and Lee 2014). Still others argue that Ab and tau may be produced as a reaction to or defense against neurodegeneration and cell death, making them questionable biomarkers and inappropriate drug targets (Lee *et al.* 2005; Mullane and Williams 2018a, 2018b; Ricciarelli and Fedele 2017). Despite the controversy and the lack of clarity, the pursuit of Ab clearance (or halting its production via secretase inhibitors) has dominated pharmacological investigations and has led to numerous randomized controlled trials. Many trial drugs have produced a measurable reduction or clearance of amyloid but have failed to bring about any substantial improvement in cognition (Table 43-1), further challenging the legitimacy of Ab as a target for drug development (Ackley *et al.* 2021; Long and Holtzman 2019; Penninkilampi *et al.* 2017; Stoiljkovic *et al.* 2021; Uddin *et al.* 2020; van Dyck 2018; Vaz and Silvestre 2020).

TABLE 43-1. Some of the major clinical trials of amyloid-targeted pharmaceutical treatments

Drug name	Sponsor	Status	Mechanism of action	Positive outcomes	Negative outcomes	Referenc
AN-1792	Pfizer/Janssen	Phase II terminated	Active immunotherapy	Reduced CSF p-tau; cognitive benefit at 4.6-year follow-up	Increased brain atrophy; increased risk of meningoencephalitis and death	Orgogoz *al.* 20
CAD106	Novartis/ Amgen	Phase II/III terminated	Active immunotherapy	Reduced CSF p-tau	Increased risk of ARIAs	Lopez e 2019
ACC001	Pfizer/Janssen	Phase II terminated	Active immunotherapy	Sustained immune response	No cognitive or functional improvement; skin lesions	Hull *et a* 2017
Affitope AD02	AFFiRiS	Phase II terminated	Active immunotherapy	Cognitive improvement, slowed hippocampal atrophy in a control group	Failed to reach primary cognitive endpoints	Schneeb *et al.*
ABvac40	Araclon Biotech	Phase II active	Active immunotherapy	Sustained immune response	Increased risk of ARIAs	AlzForu 2020
UB-311	United Neuroscience	Phase II terminated	Active immunotherapy	Modest reduction in brain Ab	Failed to reach cognitive and functional endpoints	Alzheim News Today 2019
Bapineuzumab	Pfizer/Janssen	Phase III terminated	Passive immunotherapy	Reduced CSF p-tau	Increased risk of ARIAs; no cognitive improvement	Salloway *al.* 20
Solanezumab	Eli Lilly	Phase III terminated	Passive immunotherapy	Some cognitive improvement in	Failed to reach cognitive and functional endpoints	Doody e 2014; Honig *al.* 20

Note. Ab = amyloid b; AD = Alzheimer's disease; ARIA = amyloid-related imaging abnormality; CSF = cerebrospinal fluid; MCI = mild cognitive impairm tau = phosphorylated tau.

Drug name	Sponsor	Status	Mechanism of action	Positive outcomes	Negative outcomes	Referenc
				patients with mild AD		
Ponezumab	Rinat Neuroscience/Pfizer	Phase II completed	Passive immunotherapy	No ARIA or encephalitis	Failed to reach primary cognitive endpoints	Landen 2017
Gantenerumab	Hoffmann-La Roche	Phase III terminated, reactivated	Passive immunotherapy	Nonsignificant benefit in patients with rapid clinical progression, post hoc analysis; reduction in brain Ab with high doses	Risk of ARIAs; Phase II halted after futility analysis; failed to reach primary endpoints with initial analysis	Ostrowit et al.
Aducanumab	Biogen	Phase III; FDA-approved and active	Passive immunotherapy	Significant benefit in cognitive measures with high doses, post hoc analysis; reduction in brain Ab, CSF p-tau	Risk of ARIAs; halted after futility analysis; failed to reach primary endpoints with initial analysis	Alexand al. 20
Lecanemab	Eisai/Biogen	Phase III; FDA-approved and active	Passive immunotherapy	Significant benefit in cognitive measures with high doses	Risk of ARIAs; failed to reach primary endpoints with initial analysis	Swanso al. 20
Crenezumab	Hoffmann-La Roche	Phase III terminated, reactivated	Passive immunotherapy	Significant benefit in cognitive measures with high doses, post hoc analysis	Halted after futility analysis; failed to reach primary endpoints with initial analysis	Decourt al. 20
CTS-21166	CoMentis/Astellas	Phase I completed	b-Secretase inhibitor	Decreased levels of plasma Ab	Pharmaceutical collaboration terminated	Uddin e 2020
BI 1181181	Boehringer Ingelheim	Phase I complet	b-Secretase inhibitor	Dose-dependent	Low blood-brain penetration and	AlzForu 2015

Note. Ab = amyloid b; AD = Alzheimer's disease; ARIA = amyloid-related imaging abnormality; CSF = cerebrospinal fluid; MCI = mild cognitive impairm tau = phosphorylated tau.

Drug name	**Sponsor**	**Status**	**Mechanism of action**	**Positive outcomes**	**Negative outcomes**	**Referenc**
		ed		decreased levels of plasma and CSF Ab	low oral bioavailability	
LY2886721	Eli Lilly	Phase I terminated	b-Secretase inhibitor	Reduced concentrations of cerebral Ab	Liver toxicity	Menting Claas 2014
RG7129	Roche	Phase I terminated	b-Secretase inhibitor	Decreased levels of plasma Ab	Liver toxicity	AlzForu 2013
Verubecestat	Merck	Phase III terminated	b-Secretase inhibitor	Decreased levels of CSF Ab	Worsened cognitive function	Egan *et* 2018, 2019
Elenbecestat	Eisai/Biogen	Phase II/III terminated	b-Secretase inhibitor	Decreased levels of CSF Ab	No significant improvement in cognition	Bowma Roger 2019
Umibecestat	Novartis/ Amgen	Phase II/III terminated	b-Secretase inhibitor	Decreased levels of CSF Ab	Worsened cognitive function; increased brain atrophy	Lopez *e* 2019
Lanabecestat	AstraZeneca/Eli Lilly	Phase III terminated	b-Secretase inhibitor	Decreased levels of plasma and CSF Ab	No cognitive or functional improvement	Wessels *al.* 20
Atabecestat	Janssen	Phase III terminated	b-Secretase inhibitor	Dose-dependent decreased levels of CSF p-tau	Worsened cognitive function; hepatoxicity	Henley *e* 2019
Semagacestat	Eli Lilly	Phase III completed	g-secretase inhibitor	Decreased levels of plasma Ab	Halted after futility analysis showed ineffectiveness; increased risk of skin infection, cancer	Doody *e* 2013
Avagacestat	Bristol-Myers Squibb	Phase II terminated	g-secretase inhibitor	Dose-dependent decreased levels of CSF Ab	ARIAs; gastrointestinal and dermatological side effects; worsened cognition	Coric *et* 2015
Begacestat	Pfizer	Phase I completed	g-secretase inhibitor	Decreased levels of plasma Ab	Gastrointestinal and dermatological side effects;	Stoiljko *al.* 20

Note. Ab = amyloid b; AD = Alzheimer's disease; ARIA = amyloid-related imaging abnormality; CSF = cerebrospinal fluid; MCI = mild cognitive impairm tau = phosphorylated tau.

Drug name	**Sponsor**	**Status**	**Mechanism of action**	**Positive outcomes**	**Negative outcomes**	**Referenc**
					worsened cognition	
Tarenflurbil	Myrexis	Phase III terminated	g-secretase modulator	Slowing of decline in mild AD in Phase II	Failed to demonstrate any disease-modifying effect in Phase III	Green *et* 2009
Pioglitazone	Takeda/Zinfandel	Phase III terminated	Thiazolidinediones	Some cognitive improvement in MCI	Failed to demonstrate significant benefit	Miller *e* 2011
Rosiglitazone	GlaxoSmithKline	Phase III completed	Thiazolidinediones	Some cognitive improvement in MCI	Failed to demonstrate significant benefit	Miller *e* 2011
Scyllo-inositol	Elan	Phase II completed	Ab aggregation inhibitor	Decreased levels of CSF Ab	No cognitive or functional improvement; toxicity at higher doses	Sallowa *al.* 20
Tramiprosate	Bellus Health	Phase III completed	Ab aggregation inhibitor	Slowed hippocampal atrophy, post hoc analysis	No cognitive improvement	Aisen *et* 2011

Note. Ab = amyloid b; AD = Alzheimer's disease; ARIA = amyloid-related imaging abnormality; CSF = cerebrospinal fluid; MCI = mild cognitive impairm
tau = phosphorylated tau.

Amyloid-Lowering Agents via Immunotherapy

The most extensively developed approach to removing Ab is through vaccination, which involves actively stimulating the production of endogenous antibodies as opposed to administering Ab as an antigen in order to elicit an immune response against it. Initial Alzheimer's treatment studies looking at antiamyloid immunization were considered failures because of severe side effects and the lack of significant clinical results (Gilman *et al.* 2005; Karran 2012; Pasquier *et al.* 2016; Ricciarelli and Fedele 2017). T cell-mediated meningoencephalitis was attributed to an early active vaccine (AN-1792) in 6% of patients (Gilman *et al.* 2005). Additional active vaccine studies showed improved safety and tolerability but have still failed to prove clinical efficacy.

In contrast to the limited number of studies that have investigated active immunization strategies, there has been significantly more investigation of passive immunization. Agents used in this approach are human or humanized monoclonal antibodies that bind with high affinity to aggregated Ab and promote its removal by Fc receptor-mediated phagocytosis, while showing lower affinity to monomers (Ricciarelli and Fedele 2017). Most passive immunotherapies that have reached Phase III trials were ineffective at the doses tested, failed to meet primary endpoints, and were associated with amyloid-related imaging abnormalities (ARIAs) such as edema and microhemorrhages at higher doses (Salloway *et al.* 2014). Clinical trials for gantenerumab and aducanumab were both halted after an interim futility analysis (Ostrowitzki *et al.* 2017; Sevigny *et al.* 2016). Both trials were then restarted after further analysis, with the latter agent now approved by the FDA. While lecanemab (also now FDA approved) failed to meet primary endpoints with the initial analysis (at 12 months), it did meet these endpoints with the final analysis (at 18 months). Lecanemab has been associated with increased risk for ARIAs.

Aducanumab

The FDA approved aducanumab on June 7, 2021, making it the first agent to be approved for the treatment of Alzheimer's disease since 2003. Aducanumab, a recombinant human immunoglobulin g monoclonal anti-Ab antibody that specifically targets Ab oligomers and fibrils (soluble and insoluble forms), was studied in two nearly identically designed Phase III double-blind, placebo-controlled randomized clinical trials of high and low doses (Sevigny *et al.* 2016). Although both studies were stopped for futility in March 2019, one showed clinical efficacy in reanalysis, specifically in participants treated with the higher dose and for longer periods (Alexander *et al.* 2021; Arndt *et al.* 2018; Sevigny *et al.* 2016). Reanalysis of the complete patient data showed that the one study had met its primary endpoint of slowing cognitive decline, measured via Clinical Dementia Rating Scale-Sum of Boxes (CDR-SB) scores. ^{18}F-florbetapir PET imaging showed evidence of amyloid reduction, and substudies of cerebrospinal fluid (CSF) showed a dose-related decrease in phosphorylated tau--a possible "downstream" effect of amyloid removal (Sabbagh and Cummings 2021). The accelerated FDA approval of aducanumab was contingent on verification of clinical benefit in a confirmatory trial or trials that will be allowed to run until 2030. People with early stages of Alzheimer's disease are the target population for treatment. Treatment is begun only after confirmation of an amyloid burden via ^{18}F-florbetapir PET imaging or CSF analysis.

Aducanumab (aducanumab-avwa) injection, for intravenous use, is marketed as single-use vials in strengths of 170 mg and 300 mg (Biogen Inc. 2023). Dosing is via intravenous infusion administered over approximately 1 hour every 4 weeks and at least 21 days apart. The target dose is 10 mg/kg and is reached after a titration schedule of six infusions.

Detection of the side effect of greatest concern for aducanumab--ARIAs with edema or microhemorrhage--requires monitoring with serial imaging during treatment. ARIAs were observed in 41% of patients during clinical studies. ARIAs may manifest as symptoms of headache, confusion, dizziness, vision changes, or nausea. Hypersensitivity reactions such as angioedema and urticaria have also occurred. Headache, falls, diarrhea, and altered mental status were additional adverse reactions reported by at least 2% of patients during aducanumab clinical trials. Aducanumab aims to slow the progression of Alzheimer's disease; it does not address specific symptoms or halt or cure the disease process.

There has been much criticism of aducanumab's approval. In November 2020, an 11-member expert advisory committee voted 8 against and 1 for approval; 2 were uncertain. Members against approval felt that the study failed to prove amyloid as a causative agent in Alzheimer's disease, given the substantial evidence of clearance without showing meaningful clinical improvement (Dyer 2021). Three committee members resigned in protest after the drug's approval (Mahase 2021). The post hoc reanalysis of the drug trials not only was felt to cast uncertainty on the study's validity but also was done in collaboration with the FDA, potentially compromising the agency's objectivity (Alexander *et al.* 2021). The FDA asked the U.S. Department of Health and Human Services inspector general to investigate whether there was improper contact, and the results are pending (Dyer 2021). Additional criticisms of aducanumab include the following: the drug's cost ($56,000 annually) and its impact on Medicare and health care costs in general; the lack of racial and ethnic diversity among trial participants (76% were white, 10% were Asian, and 3% were Hispanic; there was no African American representation); the uncertainty of benefit versus the certainty of ARIA risk; the lack of guidance and evidence on when to end treatment; and, finally, the risk of shutting down other avenues of research.

Lecanemab

On January 6, 2023, the FDA granted accelerated approval of lecanemab, and traditional approval followed on July 6, 2023. Lecanemab is a humanized immunoglobulin g1 monoclonal antibody that targets soluble aggregated Ab, with activity across oligomers, protofibrils, and insoluble fibrils. When studied in a randomized double-blind clinical trial, it met the primary endpoint of significant clinical change on CDR-SB scores at 18 months. Secondary endpoints were also met: a change in amyloid burden on PET and significant clinical change on the Alzheimer's Disease Assessment Scale (ADAS-cog14), the Alzheimer's Disease Composite Score (ADCOMS), and the Alzheimer's Disease Cooperative Study Activities of Daily Living Scale for Mild Cognitive Impairment (ADCS-MCI-ADL). Participants in the trial had been diagnosed with either mild cognitive impairment due to Alzheimer's disease or mild Alzheimer's disease-related dementia. Participants showed evidence of amyloid burden on PET scan or CSF testing and ranged in age from 50 to 90 years. Although efforts were made to ensure a more ethnically diverse enrollment, Black persons were still underrepresented. The most common adverse events were infusion-related reactions (26.4%), followed by ARIA with hemorrhages (17.3%) and ARIA with edema or effusion (12.6%). ARIAs were less common among ApoE e2 and ApoE e3 carriers, and while more common with ApoE e4 carriers, were most frequent with ApoE e4 homozygotes (Swanson *et al.* 2021; van Dyck *et al.* 2023).

Lecanemab is administered via a diluted intravenous infusion of 10 mg/kg over approximately 1 hour, once every 2 weeks (Esai Inc. 2023). A baseline MRI must be obtained prior to the initial treatment and prior to the 5th, 7th, and 14th infusions. If a patient reports symptoms suggestive of ARIA, clinical evaluation should be performed, including an MRI if indicated. If radiographically observed ARIA is confirmed, treatment recommendations are based on the type and severity of patient-experienced symptoms.

Criticisms of lecanemab include ongoing concerns regarding ARIA risks. While the majority of cases during the trial were asymptomatic, long-term effects have yet to be determined, and safety for individuals taking blood-thinning agents has yet to be established. There is also the questionably meaningful primary endpoint of a 0.45-point change on the CDR-SB, an 18-point scale. Health professionals express concerns that the drug will promote false hopes for significant improvements among those living with impairments. Cost also remains a concern. Many health care systems lack the infrastructure needed to administer lecanemab (i.e., staffing, PET imaging, and infusion centers). Medicare did commit to coverage following the FDA's traditional approval, contingent upon diagnosis with documented evidence of amyloid burden and physician enrollment in a Medicare-run registry. Manufacturers have listed an annual drug cost of $26,500, an expense that will impact the U.S. health care system and be unaffordable for lower-income countries, where the number of dementia cases is on the rise (Ferri and Jacob 2017; The Lancet 2022).

Cholinesterase-Related Therapies

In neurocognitive disorders, there are multiple physiological processes that destroy acetylcholine (acetylcholinesterase)-producing cells that in turn reduce cholinergic transmission in the brain (Bartus *et al.* 1982; Breijyeh and Karaman 2020; Tabet 2006). Acetylcholine is involved in processes such as memory, attention, sensory information, learning, and other critical functions. Because of acetylcholine's essential role in brain function, the cholinergic hypothesis arose in the 1970s as a contributing factor in the development of Alzheimer's disease (Bartus 2000; Breijyeh and Karaman 2020).

Acetylcholinesterase inhibitors increase acetylcholine by blocking the enzymes catalyzing its breakdown--that is, acetylcholinesterase and butyrylcholinesterase. These inhibitors can be classified as reversible, irreversible, and pseudo-reversible based on the degree of enzyme inhibition (Breijyeh and Karaman 2020; Giacobini 1998; Marucci *et al.* 2021).

Tacrine was the first acetylcholinesterase inhibitor (of both acetylcholinesterase and butyrylcholinesterase) and was approved by the FDA for Alzheimer's disease treatment in 1993. However, tacrine was discontinued in 2013 because of its significant side-effect profile, including hepatotoxicity. Donepezil, rivastigmine, and galantamine are the remaining FDA-approved acetylcholinesterase inhibitors that continue to be marketed and used to treat Alzheimer's disease (Sharma 2019). Efficacy for treatment of Alzheimer's disease is similar among acetylcholinesterase inhibitors (Arvanitakis *et al.* 2019; Birks 2006; Colovic *et al.* 2013; Seltzer 2006; Thompson *et al.* 2004).

Rivastigmine is additionally FDA approved to treat Parkinson's-related dementia. Acetylcholinesterase inhibitors are used to treat major neurocognitive disorder with Lewy bodies but are not FDA approved for this indication, so this use is considered off-label. Studies have shown statistically significant benefit but with associated adverse effects, specifically with rivastigmine and donepezil. Data for galantamine are limited (Stinton *et al.* 2015).

Acetylcholinesterase inhibitors are not FDA approved for mild neurocognitive disorders because studies have failed to show significant benefit for this condition (Arvanitakis *et al.* 2019; Cooper *et al.* 2013). Furthermore, these medications have not been approved or shown benefit for neurocognitive disorders that do not involve a

cholinergic deficit, such as frontotemporal variants, prion disease, Huntington's disease, and HIV infection.

These medications are only modestly effective in treating symptoms and do not prevent or cure neurodegenerative processes (Breijyeh and Karaman 2020). In a meta-analysis examining 80 trials of multiple acetylcholinesterase inhibitors in various forms of neurocognitive disorders, Mini-Mental State Examination results at 3, 6, and 12 months of treatment showed effect sizes of 1.08, 1.0, and 1.10 points, respectively (Knight *et al.* 2018). Research has been inconsistent in establishing preservation or improvement in functional capacity (activities of daily living) or management of adverse behaviors, but multiple studies have shown a reduced risk of nursing home placement associated with long-term acetylcholinesterase inhibitor use, specifically in Alzheimer's disease (Geldmacher *et al.* 2003; Knopman *et al.* 1996; Lopez *et al.* 2002).

The major side effects of acetylcholinesterase inhibitors are gastrointestinal, likely owing to acetylcholine being a primary gastrointestinal motility-enhancing transmitter, and occur in about 5% of users. Studies have also shown an associated risk of bradycardia (Isik *et al.* 2018), and there are case reports of an associated risk of QT interval prolongation and torsades de pointes (Malone and Hancox 2020).

Summary of Recommendations

Donepezil, rivastigmine, and galantamine are available for use orally (in tablet or capsule form, and/or as a oral solution), with a slow titration schedule over 4-8 weeks recommended for all three to minimize adverse effects, especially gastrointestinal distress. Side effects may abate at lower doses. Rivastigmine and donepezil are also available in a transdermal formulation, and donepezil additionally as an orally disintegrating tablet, allowing an alternate route when there are barriers to or difficulties with the usual routes of oral administration. In the moderate stage of a neurocognitive disorder, each acetylcholinesterase inhibitor may be used in combination with another FDA-approved pharmacological treatment, memantine. There is no clear evidence on the optimal duration of treatment with these medications (Marucci *et al.* 2021).

Donepezil

As a piperidine-based, reversible, noncompetitive acetylcholinesterase inhibitor with a plasma half-life of about 70 hours, donepezil was approved in the United States for the treatment of mild to moderate Alzheimer's disease in 1996 and for severe Alzheimer's disease in 2006. Donepezil is given once daily in a dose of 5, 10, or 23 mg. The 5-mg dose is only slightly less effective than the 10-mg dose and is an appropriate regimen for mild to moderate Alzheimer's disease, especially when tolerability is an issue (Birks and Harvey 2018). For moderate to severe Alzheimer's disease, 10-or 23-mg therapy is indicated; the 23-mg dose is generally initiated after a patient's disease has been stable for at least 3 months with the 10-mg dose. A 2018 Cochrane Review showed that benefits obtained with the 23-mg dose were no greater than those with the 10-mg dose, and the benefits of the 10-mg dose were only marginally better than those with the 5-mg dose (Birks and Harvey 2018). An extended-release capsule formulation containing both memantine and donepezil (Namzaric) has been available since 2014 for moderate to severe Alzheimer's disease.

Rivastigmine

Rivastigmine, a carbamyl derivative, is a slowly reversible inhibitor of acetylcholinesterase and butyrylcholinesterase with an elimination half-life of approximately 2 hours. It was approved in 2000 for use in the

United States and was indicated for the treatment of mild to moderate dementia of Alzheimer's and Parkinson's disease. In 2007, a rivastigmine 24-hour topical patch in dosages of 4.6, 9.5, and 13.3 mg/24 hours became the first transdermal patch to receive FDA approval for the treatment of mild to moderate Alzheimer's disease. In 2013, the FDA extended its approval for the higher dosage form (the 13.3-mg/24-hour dosage transdermal system) to include treatment of severe Alzheimer's disease. A 2015 Cochrane Review confirmed rivastigmine's benefit in the treatment of mild to moderate Alzheimer's disease but did not review the higher-dosage patch for severe stages of disease (Birks and Grimley Evans 2015). Rivastigmine inhibits the G1 isoenzyme of acetylcholinesterase selectively up to four times more potently than it does the G4 isoenzyme (Enz *et al.* 1993). This unique compound, with its butyrylcholinesterase inhibition properties, has been postulated to be of greater benefit than other acetylcholinesterase inhibitors in the treatment of Alzheimer's disease because butyrylcholinesterase activity increases in the hippocampus and cortex, whereas acetylcholinesterase activity diminishes (Tasker *et al.* 2005). To date, this effect has not been conclusively shown to be of clinical significance (Noetzli and Eap 2013). However, as a treatment involving multiple target receptor sites, this agent does have a theoretical advantage over single-target approaches. Rivastigmine capsules are available in doses of 1.5, 3, 4.5, and 6 mg, and the 24-hour transdermal patch is available in dosages of 4.6, 9.5, and 13.3 mg/24 hour. Transdermal administration and patches delivering a lower dosage compared with the pill form result in reduced side effects (especially gastrointestinal). A previously available rivastigmine oral solution product is not currently marketed in the United States.

For Alzheimer's disease, rivastigmine is initiated at 1.5 mg bid, taken orally. If tolerated, the dosage is increased every 2 weeks, first to 3 mg bid and then to 4.5 mg bid, up to a maximum dosage of 6 mg bid. Transdermal therapy is initiated at one 4.6-mg patch applied daily for at least 4 weeks, at which time the dosage may be increased to the 9.5-mg daily patch. Dosage may be further increased to 13.3 mg for severe stages of Alzheimer's disease. For Parkinson's disease, the oral rivastigmine dosage is increased as described for Alzheimer's disease, except that the minimum interval is extended to every 4 weeks (rather than every 2 weeks), up to a maximum dosage of 6 mg bid.

Galantamine

Galantamine hydrobromide (a tertiary alkaloid) is a specific, competitive, and reversible acetylcholinesterase inhibitor with a plasma half-life of 6-8 hours that was first marketed in the United States in 2001 as a treatment for mild to moderate dementia of Alzheimer's disease. Galantamine is unique in that it modulates neuronal nicotinic receptors (Coyle and Kershaw 2001). Whether this nicotinic receptor modulation imparts any significant clinical benefit in disease modification remains unknown. Oral dosing with galantamine tablets is initiated at 4 mg bid, with an increase after a minimum of 4 weeks to 8 mg bid as tolerated. The optimal dosage range is 16-24 mg/day. The extended-release galantamine capsule formulation for once-daily dosing has efficacy and side effects similar to that of the twice-daily dosing formulation; it is generally initiated at a dosage of 8 mg/day (taken in the morning), increased to 16 mg/day after a minimum interval of 4 weeks, and (if well tolerated after a minimum of 4 additional weeks) then increased to 24 mg/day. An oral solution (4 mg/mL) is available as well. Pooled data from early trials in patients with mild impairment showed significantly higher rates of death attributable to bronchial carcinoma, cerebrovascular disorder/syncope, myocardial infarction, and suicide in the galantamine-treated groups (Cusi *et al.* 2007; Loy and Schnieder 2006), although the use of cholinesterase inhibitors, including galantamine, reduced the risk of myocardial infarction and death in a different study (Nordstrom *et al.* 2013). Multiple studies of galantamine administered alone, with antipsychotic medication, with memantine, and a combination of all three have shown promise in the treatment of patients with schizophrenia (Koola 2016, 2018; Koola *et al.* 2014, 2020; Lee *et al.* 2007).

N-Methyl-D-Aspartate-Related Therapies

Glutamate is an agonist of kainite, *N*-methyl-D-aspartate (NMDA), and amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors. Neuronal plasticity of memory and learning is influenced by glutamate's direct modulation of the NMDA postsynaptic receptor. Glutamate acts as an excitatory neurotransmitter activating the NMDA receptor. Glutamate excess results in neurotoxicity, affecting cognitive functioning (Koch *et al.* 2005).

Summary of Recommendations

Memantine has been shown to reduce the level of cognitive impairment in patients with moderate to severe Alzheimer's disease (Bullock 2006; Nakamura *et al.* 2014; Reisberg *et al.* 2003). Initiation may be considered especially when acetylcholinesterase inhibitors have not been tolerated. Memantine in combination with an acetylcholinesterase inhibitor is an appropriate consideration for improvement in cognition and behavior. There is limited to poor evidence for memantine as a treatment for other neurocognitive disorders (McShane *et al.* 2019).

Memantine

Memantine is a noncompetitive NMDA receptor antagonist approved in the United States for the treatment of moderate to severe Alzheimer's disease. The NMDA receptor modulates memory function. Memantine's low-affinity antagonism of glutamate, which has been linked to neurodegeneration and excitotoxicity, may protect against neurotoxicity (Lipton and Rosenberg 1994).

Memantine is available in tablets, in extended-release capsules, and as an oral solution. It is recommended that memantine tablets be initiated at a dosage of 5 mg/day for 1 week and increased weekly by 5 mg/day up to a target dosage of 20 mg/day. Memantine tablets are generally given in twice-daily doses, although the elimination half-life ranges from 60 to 80 hours. Memantine is also available in a once-daily extended-release capsule formulation (7, 14, 21, and 28 mg); it is recommended that memantine capsules be initiated at a dosage of 7 mg/day for 1 week, increasing by 7 mg/day after a minimum of 1 week to 14 mg/day, up to a target dosage of 28 mg/day. Memantine

dosing should be adjusted for patients with moderate to severe renal impairment, with a target of 14 mg/day. The most common adverse effects are drowsiness, dizziness, confusion, headache, and constipation.

Memantine Combination Therapy

Memantine in combination with an acetylcholinesterase inhibitor has been shown to improve cognitive domains and to ameliorate symptoms of behavioral dyscontrol (agitation/aggression, eating/appetite, irritability/lability) (Cummings *et al.* 2006; Schmidt *et al.* 2015; Tariot *et al.* 2004). Given the disruption of multiple neurotransmitter systems and pathways in neurocognitive disorders, the use of adjunctive cognition-enhancing medications is understandable (Grossberg *et al.* 2006; Koola *et al.* 2014). The specific neurobiological deficits that may be affected by a pharmacological or nutraceutical intervention should be considered. In 2014, fixed-dosage combinations of extended-release memantine (14 or 28 mg) and donepezil (10 mg) became available. Patients without severe renal impairment who are currently taking donepezil 10 mg/day and extended-release memantine 10 mg bid or 28 mg once daily may be switched to the memantine 28 mg/donepezil 10 mg combination tablet, which can be taken once daily.

Vascular and Inflammation-Related Therapies

Major known modifiable risk factors for cognitive impairment (with or without dementia) include diabetes mellitus, hypertension, cardiac ischemia, atrial fibrillation, smoking, hyperlipidemia, and peripheral vascular disease (Desmond *et al.* 1993; Rockwood *et al.* 1997). Controversial risk factors include hyperhomocysteinemia. Established vascular therapeutic interventions have included low-dose aspirin and other antiplatelet agents, anticoagulants, antihypertensives, aggressive management of diabetes, carotid endarterectomy for selected patients, and treatment of hyperlipidemia. There is a significant overlap of patients with vascular cognitive impairment and those with Alzheimer's disease (Gearing *et al.* 1995; O'Brien 1994). Cholinergic receptors (muscarinic and nicotinic) are known modulators of cerebral blood flow (Schwarz *et al.* 1999; Zhang *et al.* 1998). However, the notion of overlap has been challenged by evidence that the cholinergic system may be intact in individuals with "pure" vascular dementia but be compromised to the same extent as in Alzheimer's disease in individuals with a mixed etiology of both Alzheimer's and vascular disease (O'Brien and Thomas 2015). Currently, a large burden of vascular disease pathology (large-vessel to microvascular disease and focal, multifocal, or diffuse lesions) in the absence of other neurodegenerative processes, as well as a clear relation of the cognitive decline or progression to the lesions, is needed to make a diagnosis of a vascular neurocognitive disorder. Vascular pathology should otherwise be considered as contributory to impairment and not the primary cause (O'Brien and Thomas 2015).

The effectiveness of acetylcholinesterase inhibitors and memantine in treating vascular dementia has been insufficient to support these agents' widespread use. There is currently no FDA-approved treatment for vascular dementia. A 2021 Cochrane Review specifically examined acetylcholinesterase inhibitors, with three trials studying donepezil, three studying rivastigmine, and two studying galantamine. There was moderate to high certainty of evidence for a slight effect on cognition for donepezil

and galantamine, but the size of the change was unlikely to register as clinically beneficial. The evidence for rivastigmine was less certain and was determined to need more research, especially regarding the transdermal form (Battle *et al.* 2021).

There is limited evidence that managing vascular risk factors lowers the risk for vascular cognitive impairment. There have been mixed results in studies on blood pressure and glycemic and cholesterol control. The use of aspirin, other nonsteroidal anti-inflammatory drugs, or statins to prevent and treat vascular dementia is currently not well supported by the literature (Iadecola *et al.* 2019; Jaturapatporn *et al.* 2012; McGuinness *et al.* 2016).

Other Therapies

Antioxidant-related treatment for cognitive impairment remains poorly supported by placebo-controlled, double-blind studies. *Ginkgo biloba* could be classified within several potential treatment categories, including antioxidants, nutraceuticals, cholinergic agents, and vasodilators; most studies have shown no to only marginal benefit for this agent (Laws *et al.* 2012). Vitamin E (including tocopherols and tocotrienols), vitamin C, and carotenoids have antioxidant properties; however, reports of benefit in treating patients with cognitive impairment are mixed. Although antioxidants may have potential as a combination therapy modality, further research is required before endorsing specific treatment recommendations with current antioxidants.

Various other agents are being tested and studied for their potential to improve cognitive impairment. Examples include anti-tau therapies (most are immunotherapies, but only an aggregation inhibitor has reached Phase III status), tramiprosate, modafinil, hormone replacement therapy, nutraceuticals (e.g., *Rubia cordifolia*, *Salvia lavandulaefolia*, *Rosmarinus officinalis*, *Melissa officinalis*), dehydro-3-epiandrosterone, aniracetam, piracetam, latrepirdine, and unifiram. Currently, no recommendations can be made for use of any of these agents as monotherapy or combination therapy.

Conclusion

The molecular pathogenesis of nerve cell death remains elusive, especially as it relates to the onset and progression of cognitive impairment. Alzheimer's disease and other types of cognitive impairment represent a wide spectrum of neurosystem dysfunction, and no single treatment modality yet found is sufficient to address the global apoptosis and degeneration that occur. Combination therapies (pharmacodynamically exerting multiple effects on disease pathology) have proven successful in the treatment of cancer and HIV infection. The same synergistic approach to treating neurocognitive disorders may be required (Campos *et al.* 2016; Cummings *et al.* 2019; Salloway *et al.* 2020; Tomaszewski *et al.* 2016).

As it has become clearer that neurodegeneration often precedes the manifestation of cognitive deficits, accurate assessment of individual genetic risk followed by routine approved biomarkers may lead to very targeted, disease-altering treatment even in the prodromal stage of the disease (Ghosh *et al.* 2020).

CHAPTER 44

Sedative-Hypnotics

Seiji Nishino, M.D., Ph.D.
Taisuke Ono, M.D., Ph.D.
Naoya Nishino, M.D.
Noriaki Sakai, D.V.M., Ph.D.
Emmanuel Mignot, M.D., Ph.D.

In this chapter we examine some of the pharmacological properties of benzodiazepines, barbiturates, and other sedative-hypnotic compounds, including orexin (hypocretin) receptor antagonists and melatonin receptor agonists (Figure 44-1). Sedative drugs moderate excitement, decrease activity, and induce calmness, whereas hypnotic drugs produce drowsiness and facilitate the onset and maintenance of a state that resembles normal sleep in its electroencephalographic characteristics. Although these agents are CNS depressants, they usually produce therapeutic effects at dosages much lower than those that cause coma and generalized depression of the CNS.

FIGURE 44-1. History of sedative-hypnotic development.

Some sedative-hypnotic drugs have other therapeutic uses as muscle relaxants (especially benzodiazepines), antiepileptics, or preanesthetic medications. Although benzodiazepines are used widely as antianxiety drugs, it is not known whether their effect on anxiety is truly distinct from their sleep-inducing effect.

Sedative-hypnotics are also important drugs to neuroscientists. These substances modulate basic behaviors such as arousal and response to stress. Through our increasing understanding of the molecular structure of the GABA type A ($GABA_A$) receptor, the cellular mechanisms of these compounds' modes of action have been elucidated.

In 2000, it was discovered that human narcolepsy-cataplexy was associated with deficiency of a newly discovered neuropeptide, orexin (or hypocretin) (Nishino *et al.* 2000). Although replacement therapies for the orexin-deficient narcolepsy using synthetic small-molecule orexin receptor agonists are not yet available, dual orexin receptor antagonists have been developed and were approved by the FDA in 2014 for the treatment of insomnia.

Further understanding of their mode of action could thus help to elucidate neurochemical and neurophysiological control of sleep and sleep-related physiology and behaviors.

Benzodiazepines and Benzodiazepine-Like Agents

History and Discovery

Benzodiazepines were first synthesized in the 1930s. The introduction of chlorpromazine and meprobamate in the early 1950s led to a decade of development of sophisticated in vivo pharmacological screening methods that were used to identify the sedative properties of benzodiazepines. More than 3,000 benzodiazepines have been synthesized since chlordiazepoxide (synthesized by Sternbach in 1957; see Baenninger 2004) was introduced into clinical medicine. About 40 of them are in clinical use.

Several drugs chemically unrelated to the benzodiazepines have been shown to exhibit sedative-hypnotic effects with a benzodiazepine-like profile, and these drugs have been found to act via the benzodiazepine binding site on the $GABA_A$ receptor (see "Molecular Mechanism of $GABA_A$-Benzodiazepine Receptor Interaction" section later in this chapter).

Most benzodiazepines currently on the market were selected for their high anxiolytic potential rather than their CNS depressant effects. Nevertheless, all benzodiazepines

have sedative-hypnotic properties to various degrees, and some compounds that facilitate sleep have been used as hypnotics.

Mainly because of their remarkably low capacity to produce fatal CNS depression, benzodiazepines have displaced barbiturates as the preferred sedative-hypnotic agents.

Structure-Activity Relations

The term *benzodiazepine* refers to the portion of the structure composed of benzene rings (*A* in the top portion of Figure 44-2) fused to a seven-membered diazepine ring (*B*). However, most of the older benzodiazepines contain a 5-aryl substituent *(C)* and a 1,4-diazepine ring, and the term has come to mean the 1,4-benzodiazepines.

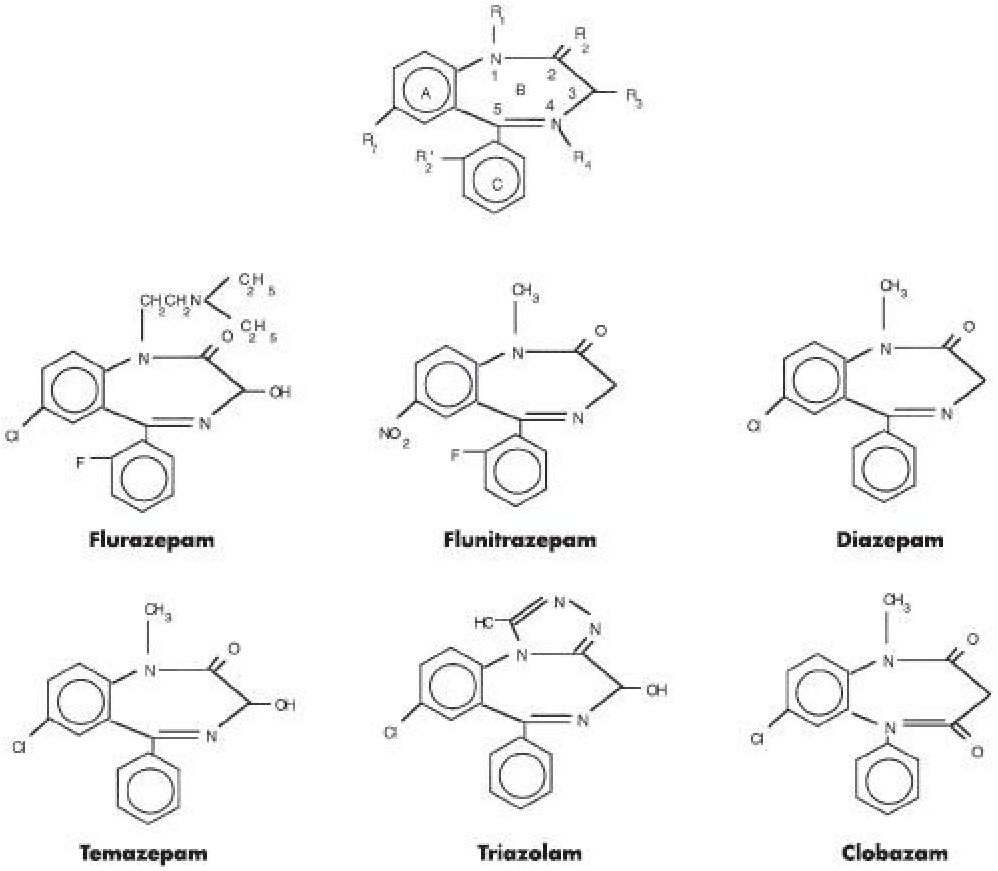

FIGURE 44-2. Chemical structures of some commonly used benzodiazepines.

The term *benzodiazepine* refers to the portion of the structure composed of benzene rings (*A* in the top portion of figure) fused to a seven-membered diazepine ring (*B*). However, most of the older benzodiazepines contain a 5-aryl substituent *(C)* and a 1,4-diazepine ring, and the term has come to mean the 1,4-benzodiazepines.

A substituent (most often chloride) at position 7 is essential for biological activity. A carbonyl at position 2 enhances activity and is generally present. Most of the newest products, such as flurazepam, also substitute the 2 position. These general features are important for the metabolic fate of the compounds. Because the 7 and 2 positions of the molecule are resistant to all major degradative pathways, many of the metabolites retain substantial pharmacological activity.

Pharmacological Profile

Benzodiazepines share anticonvulsant and sedative-hypnotic effects with the barbiturates. In addition, they have a remarkable ability to reduce anxiety and aggression (Cook and Sepinwall 1975). In the mammalian CNS, two subtypes of benzodiazepine omega (o) receptors have been pharmacologically recognized. Benzodiazepine o_1 receptors are sensitive to b-carbolines, imidazopyridines (e.g., zolpidem), and triazolopyridazines. Benzodiazepine o_2 receptors have low affinity for these ligands but high affinity for benzodiazepines. Benzodiazepine o_1 sites are enriched in the cerebellum, whereas o_2 sites are present mostly in the spinal cord, and both receptor subtypes are found in the cerebral cortex and hippocampus. Benzodiazepine o_1 and o_2 receptor subtypes are also located peripherally in adrenal chromaffin cells.

Another benzodiazepine subtype, o_3, was identified and is commonly called the peripheral benzodiazepine receptor subtype because of its distribution on glial cell membranes in nonnervous tissues such as adrenal, testicular, liver, heart, and kidney. This subtype was later detected in the CNS, especially on the mitochondrial membrane, and not in association with GABA$_A$ receptors (Gavish *et al.* 1992). The o_3 receptor subtype has high affinity for benzodiazepines and isoquinoline carboxamides (Awad and Gavish 1987). The functional role of this receptor subtype is unknown, but it may be involved in the biosynthesis and mediation of the sedative-hypnotic effects of certain neuroactive steroids (e.g., pregnenolone, dehydroepiandrosterone, allopregnanolone, tetrahydrodeoxycorticosterone) (Edgar *et al.* 1997; Friess *et al.* 1996; Rupprecht *et al.* 1996). Neurosteroids modulate GABA$_A$-mediated transmission through an allosteric mechanism that is distinct from the modulation mechanism of benzodiazepines and barbiturates. Through stimulation of o_3 receptors with agonists, cholesterol is transferred from intracellular stores in mitochondria and becomes available to the mitochondrial cytochrome P450 (CYP) cholesterol side chain cleavage enzyme, and neurosteroid biosynthesis begins (Papadopoulos *et al.* 2001). Benzodiazepine o_3 receptor subtypes also may serve as mitochondrial membrane stabilizers and protect against pathologically induced mitochondrial and cell toxicity (Papadopoulos *et al.* 2001).

The $GABA_A$ receptor is a ligand-gated ion channel that mediates fast synaptic neurotransmission in the CNS. When the $GABA_A$ receptor is occupied by GABA or GABA agonists such as muscimol, the chloride channels open and chloride ions diffuse into the cell. Early research established that diazepam (and related benzodiazepines) does not act directly through GABA but instead modulates inhibitory transmission through the $GABA_A$ receptor in some other way. It was subsequently discovered that benzodiazepines bind specifically to neural elements in the mammalian brain with high affinity and that an excellent correlation exists between drug affinities for these specific binding sites and in vivo pharmacological potencies (Mohler and Okada 1977; Squires and Brastrup 1977).

The binding of a benzodiazepine to the $GABA_A$ receptor site is enhanced in the presence of GABA or a GABA agonist, suggesting that a functional (but independent) relationship exists between the $GABA_A$ receptor and the benzodiazepine receptor binding sites (Tallman *et al.* 1978). Barbiturates (and to some extent alcohol) also seem to produce anxiolytic and sedative effects at least partly by facilitating GABAergic transmission (see "Barbiturates" section later in this chapter). This common action for chemically unrelated compounds can be explained by the shared ability of these compounds to stimulate specific sites on the $GABA_A$ receptor.

The benzodiazepines bind with high affinity to their binding sites so that the action of GABA at its receptor site is allosterically enhanced. GABA can produce stronger postsynaptic inhibition in the presence of a benzodiazepine. Benzodiazepine agonists are assumed to potentiate only ongoing physiologically initiated actions of GABA (at $GABA_A$ receptors), whereas barbiturates are thought to cause inhibition at all GABAergic synapses regardless of their physiological activity. In addition, barbiturates appear to increase the duration of the open state of the chloride channel, whereas benzodiazepines increase the frequency of channel openings but have little effect on duration (Twyman *et al.* 1989). These fundamental differences between the allosteric effects of benzodiazepines within the $GABA_A$ receptor and the conducive effects of barbiturates on the chloride ion channel may explain why low dosages of barbiturates have a pharmacological profile similar to that of benzodiazepines, whereas high dosages of barbiturates cause a profound and sometimes fatal suppression of brain synaptic transmission. It is notable that selective $GABA_A$ receptor agonists, such as muscimol, have no sedative or anxiolytic properties; thus, the entire $GABA_A$-benzodiazepine receptor complex must be involved for expression of sedative-hypnotic properties.

Molecular Mechanism of $GABA_A$-Benzodiazepine Receptor Interaction

The structure of the $GABA_A$-benzodiazepine receptor complex (Figure 44-3) was elucidated through the cloning of all of the implicated subunit genes and the study of the corresponding encoded proteins. The $GABA_A$ receptor is a pentameric protein consisting of five subunits that form a rosette surrounding a transmembrane ion channel pore for $Cl^{[?]}$ (see Figure 44-3A). The $GABA_A$ receptor in humans includes the following known subunits: a_1-a_6, b_1-b_4, g_1-g_4, d, e, p, and t (seven kinds of subunits, 18 isoforms total) (Mehta and Ticku 1999). Two alternatively spliced versions of the g_2 subunit, g_{2S} and g_{2L}, are also known to exist (Kofuji *et al.* 1991).

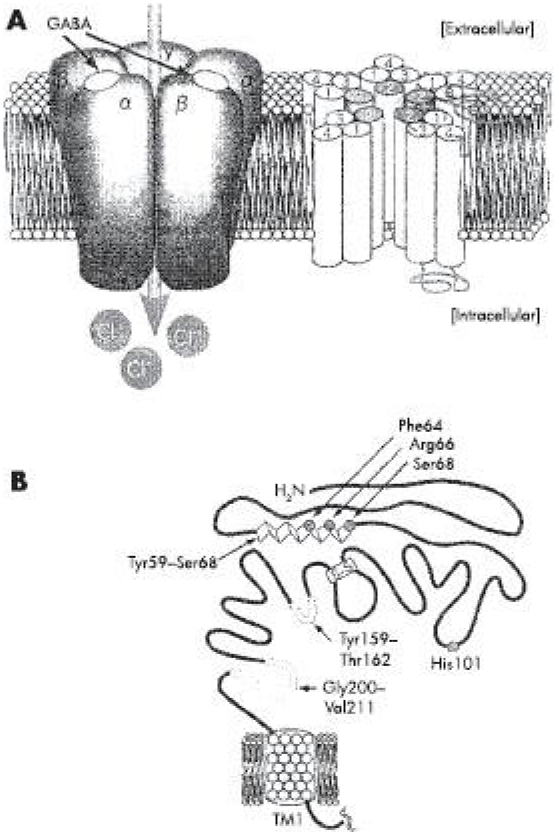

FIGURE 44-3. GABA$_A$-benzodiazepine receptor complex.

(A) Schematic model of the mammalian GABA$_A$ receptor embedded in the cell membrane, containing the a, b, and g subunits (in a ratio of 2:2:1). The binding of two molecules of GABA *(arrows)* to the action site (composed of a and b subunits) triggers the opening of the chloride channel pore, causing chloride ions (Cl$^{[?]}$) to diffuse into the cell. Each a or b subunit is composed of four transmembrane (TM) regions (TM1-TM4). The ion channel central pore is lined by TM2 regions contributed by five subunits, arranged in a rosette formation. **(B)** Structure of the a$_1$ subunit, with amino acid sequence, indicating amino acid residues implicated in GABA and benzodiazepine binding domains.

Source. Modified from Ueno *et al.* 2001.

Despite many studies, the physiological and neuroanatomic processes mediating benzodiazepine action on the GABA$_A$ receptor complex remain poorly understood. One reason is that the GABAergic system is the most widespread of all inhibitory neurotransmitter systems and could be involved in many circuits responsive to various effects of benzodiazepine agonists. In addition, the various GABA$_A$ receptor subtypes have different ligand affinities and channel functions in response to benzodiazepine agonists. These GABA$_A$ receptor subtypes are broadly distributed in various brain areas to form a mosaic of receptor subtypes (Wisden and Stephens 1999), making it difficult to understand the functional mechanisms of interaction of benzodiazepine agonists with the GABA$_A$-ergic system from the physiological point of view (Rudolph *et al.* 1999). However, site-directed mutagenesis and gene knock-in techniques have identified several important features of the benzodiazepine action sites on GABA$_A$ receptors and their physiological functions (Ueno *et al.* 2001).

It is postulated that the binding of GABA to *N*-terminal extracellular domains of a and b subunits causes conformational changes within the subunits. Ion channel pores subsequently open, and Cl$^{[?]}$ flows across the neuronal membrane, resulting in neuronal inhibition (Amin and Weiss 1993; Boileau *et al.* 1999; Sigel *et al.* 1992; Smith and Olsen 1994) (see Figure 44-3A). The extracellular domains of the a and g subunits, which consist of about 220 amino acids in the *N*-terminal region, also have been shown to bind GABA and benzodiazepines. "Pharmacologically classified" o$_1$ and o$_2$ receptors are now thought to correspond to GABA$_A$ receptors possessing the a$_1$ and a$_2$ subunits and the a$_3$ and a$_5$ subunits, respectively.

Extracellular benzodiazepine binding sites on these subunits consist of several divided portions (see Figure 44-3B). His101, Tyr159-Thr162, and Gly200-Val211 on a$_1$ subunits, as well as Lys41-Trp82 and Arg114-Asp161 on g$_2$ subunits, are essential to formation of the binding pockets (Boileau *et al.* 1998). Most strikingly, His101 is a critical residue for diazepam to exert its sedative effect (Crestani *et al.* 2001; Low *et al.* 2000; McKernan *et al.* 2000; Rudolph *et al.* 1999). Knock-in mice with displacement of His101Arg are insensitive to benzodiazepine-induced allosteric modulation of the complex but have preserved physiological regulation by GABA

(Rudolph *et al.* 1999). These knock-in mice were not sedated by diazepam but retained other effects of diazepam, such as the drug's anxiolytic-like, myorelaxant, motor-impairing, and ethanol-potentiating effects. This finding suggests the possibility that the sedative action of the benzodiazepine is mediated through $GABA_A$ receptors possessing the a_1 subunit. It is also noteworthy that the His101Arg knock-in mice responded to diazepam and showed sleep changes similar to those seen in wild-type mice, despite the lack of sedative response in these animals (Tobler *et al.* 2001). Thus, the hypnotic and sedative effects of benzodiazepines may be mediated via different subtypes, with hypnotic effects involving $GABA_A$ receptors possessing subunits other than a_1 (i.e., a_2, a_3, or a_5) (Tobler *et al.* 2001).

Nonbenzodiazepine Hypnotics (Acting on the Benzodiazepine Receptor)

Until about 1980, it was widely accepted that the benzodiazepine structure was a prerequisite for the compound's anxiolytic profile and for benzodiazepine receptor recognition and binding. However, more recently, three chemically unrelated drugs--the imidazopyridine zolpidem, the cyclopyrrolone zopiclone (which is not FDA approved, although its *S*[+]-enantiomer, eszopiclone, is FDA approved), and the pyrazolopyrimidine zaleplon--have been shown to be useful sedative-hypnotics with benzodiazepine-like profiles (Figure 44-4). Other chemical classes of drugs that are structurally dissimilar to the benzodiazepines (e.g., triazolopyridazines) but act through the benzodiazepine receptor also have been developed and have demonstrated anxiolytic activity in humans.

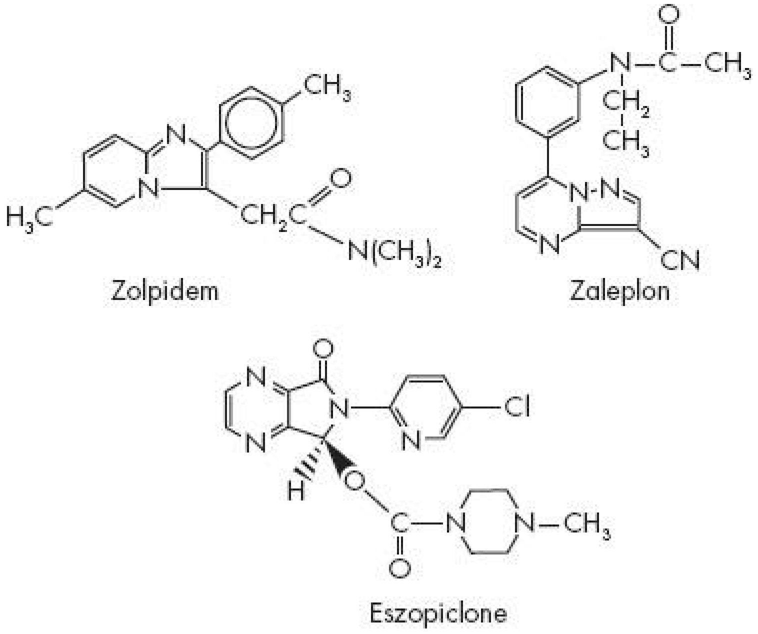

FIGURE 44-4. Nonbenzodiazepine hypnotics.

Three drugs chemically unrelated to the benzodiazepines--zolpidem (an imidazopyridine), eszopiclone (a cyclopyrrolone), and zaleplon (a pyrazolopyrimidine)--are useful sedative-hypnotics with benzodiazepine-like profiles.

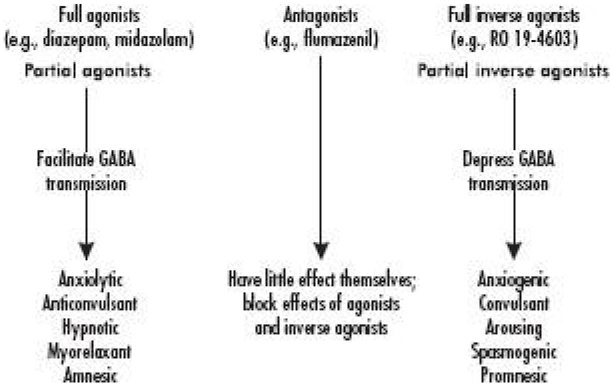
Nonbenzodiazepine hypnotics have a pharmacological profile slightly different from that of classic benzodiazepines. For example, zolpidem binds selectively to o_1 (the 50% inhibitory concentration [IC_{50}] ratio for o_1/o_2 is nearly 1:10) and has more prominent sedative-hypnotic properties relative to other properties such as anxiolytic activity or muscle relaxation. Zolpidem and zopiclone have short half-lives (3 hours and 6 hours, respectively). These drugs appear not to appreciably affect the rapid eye movement (REM) sleep pattern, whereas the amount of slow-wave sleep (SWS) may be slightly increased (Jovanovic and Dreyfus 1983; Shlarf 1992). Rebound effects (insomnia, anxiety), which are commonly seen after withdrawal of short-acting benzodiazepines, are minimal for zolpidem and zopiclone. These compounds also induce little respiratory depression and have less abuse potential than do the common clinical benzodiazepine hypnotics. However, much longer clinical trials are needed to definitively determine whether the imidazopyridines or cyclopyrrolones have any significant advantages over the short-to medium-half-life benzodiazepines in the treatment of insomnia. Eszopiclone, the active stereoisomer of zopiclone with a longer half-life, was approved by the FDA in 2004 and is thought to be helpful in sleep maintenance as well as sleep induction. Because eszopiclone induces little tolerance, it is suitable for long-term use.

Zaleplon, a pyrazolopyrimidine, also has been developed as a novel nonbenzodiazepine hypnotic (see Figure 44-4). Clinical trials demonstrated that zaleplon is a well-tolerated, safe, rapidly acting, and effective sedative with advantages over lorazepam in regard to unwanted cognitive and psychomotor impairment (Allen *et al.* 1993; Beer *et al.* 1994).

Benzodiazepine Antagonists, Partial Agonists, and Inverse Agonists

As knowledge of the relation between the structure of benzodiazepine receptor ligands and their pharmacological properties has increased, potent receptor agonists that stimulate the receptor and produce pharmacological effects qualitatively similar to those of the classic benzodiazepines have been developed. Antagonists, which block the effects of the agonists without having any effects themselves, and partial agonists, which have a mixture of agonistic and antagonistic properties, also have been introduced (Haefley 1988). Development of partial agonists may be particularly important in the future because these compounds are free of the ataxic and amnesic side effects commonly associated with the classic benzodiazepine hypnotics.

Braestrup and Nielsen (1986) found that a group of nonbenzodiazepine compounds, the b-carbolines, not only antagonized the action of the full agonists but also had intrinsic activity themselves. These compounds are called benzodiazepine inverse agonists because they have biological effects exactly opposite those of the pure agonists while also having intrinsic activity like that of agonists. The effects of inverse agonists are blocked by antagonists; thus, the benzodiazepine receptor is unique in that it has a bidirectional function (Figure 44-5).



Full agonists
(e.g., diazepam, midazolam)
Partial agonists
Facilitate GABA transmission
Anxiolytic
Anticonvulsant
Hypnotic
Myorelaxant
Amnesic
Antagonists
(e.g., flumazenil)
Have little effect themselves; block effects of agonists and inverse agonists
Full inverse agonists
(e.g., RO 19-4603)
Partial inverse agonists
Depress GABA transmission

Convulsant
Arousing
Spasmogenic
Promnesic

FIGURE 44-5. Properties of the various types of benzodiazepine receptor ligands.

Natural Ligands for Benzodiazepine Receptors in the Brain

The presence of benzodiazepine receptors in the brain suggests that natural ligands modulate GABAergic transmission through these sites. Small amounts of endogenous

benzodiazepines (e.g., diazepam, desmethyldiazepam) can be detected in human and animal tissues. These benzodiazepines probably originate from plants, such as wheat, corn, potatoes, or rice, and the levels that are detected are too low to be pharmacologically active (e.g., diazepam, < 1 ng/g; desmethyldiazepam, 0.5 ng/g).

Other endogenous benzodiazepine-like substances with neuromodulatory effects probably exist in mammals. Endogenous ligands called diazepam binding inhibitors, or endozepines, that bind to the benzodiazepine site on the $GABA_A$-ergic receptor complex were identified and isolated (Costa and Guidotti 1991; Marquardt *et al.* 1986; Rothstein *et al.* 1992). Like benzodiazepines, these ligands potentiate $GABA_A$ receptor-mediated neurotransmission by acting as positive allosteric modulators (PAMs) of this receptor. Endozepines are present in the brain at pharmacologically active concentrations and may play a role both physiologically (e.g., regulation of memory, sleep, and learning) and pathologically (e.g., panic attacks, hepatic encephalopathy) (Mullen *et al.*

1990; Nutt *et al.* 1990). Finally, endozepines have been implicated in idiopathic recurring stupor, a neurological condition characterized by recurrent episodes of stupor or coma in the absence of any known toxic, metabolic, or structural brain damage (Cortelli *et al.* 2005). Endozepine concentrations are greatly elevated in the plasma of individuals with this condition, and stupor can be interrupted by injections of flumazenil, a benzodiazepine antagonist. Thus, the roles of endozepines in physiological and pathological processes should be elucidated once these endogenous ligands have been isolated and characterized (Farzampour *et al.* 2015; Rothstein *et al.* 1992).

Recently it was reported that activities of substances in cerebrospinal fluid (CSF) that augment inhibitory GABA signaling are enhanced in patients with hypersomnia (Rye *et al.* 2012). The authors demonstrated that in the presence of GABA, CSF can stimulate $GABA_A$ receptor function in vitro (measures of $GABA_A$ receptor-mediated chloride currents in recombinant pentameric human $GABA_A$ receptor-expressed cultured cells). Interestingly, stimulations of $GABA_A$ receptor function by CSF from patients with hypersomnolence (individuals with idiopathic hypersomnia with and without long sleep, long sleepers, and individuals with narcolepsy without cataplexy) were significantly enhanced in comparison to CSF from control subjects. This bioactive CSF component had a mass of 500-3,000 daltons and was neutralized by trypsin. Flumazenil, a benzodiazepine receptor antagonist, reversed enhancement of

$GABA_A$ signaling by hypersomnolent CSF in vitro, and also normalized vigilance in all seven hypersomnolent patients who underwent the drug challenge (Rye *et al.* 2012). The authors conclude that a naturally occurring substance in CSF augments inhibitory GABA signaling, revealing a new pathophysiology associated with hypersomnia; the results also suggest the existence of other endogenous $GABA_A$ receptor modulators in the CNS.

Pharmacokinetics and Disposition

Benzodiazepines

Benzodiazepines are generally absorbed rapidly and completely. Plasma binding is high (e.g., about 98% for diazepam).

Benzodiazepines are very lipophilic (except for oxazepam), and penetration into the brain is rapid. For swift onset of action, diazepam is available as an emulsion that is administered intravenously for rapid control of epilepsy; midazolam is a water-soluble benzodiazepine suitable for intravenous injection.

The major metabolic pathways for the 1,4-benzodiazepines are shown in Figure 44-6. Medazepam is metabolized to diazepam, which is *N*-desmethylated to desmethyldiazepam. Chlordiazepoxide is also partly converted to desmethyldiazepam. Clorazepate is transformed to desmethyldiazepam.

FIGURE 44-6. Metabolic pathways for the principal 1,4-benzodiazepines.

Solid arrows and *broken arrows* denote major and minor pathways, respectively; commercially available drugs are underscored. Flurazepam, flunitrazepam, nitrazepam, and triazolam have separate metabolic pathways.

Desmethyldiazepam is a critical metabolite for biological activity because of its long half-life (> 72 hours). Because diazepam's half-life is about 36 hours, the concentration of its desmethyl derivative soon exceeds that of the parent drug during long-term administration. Desmethyldiazepam undergoes oxidation to oxazepam, which (like its 3-

hydroxy analog temazepam) is rapidly conjugated with glucuronic acid and excreted.

Among the various benzodiazepines, triazolam has a particularly short half-life (< 4 hours), and flurazepam and nitrazepam both have long half-lives. A major active metabolite of flurazepam, *N*-desalkylflurazepam, has a very long half-life (~ 100 hours).

Because benzodiazepines are often prescribed for long periods, their long-term pharmacokinetics are particularly important. Concentrations of diazepam and desmethyldiazepam reach a plateau after a few weeks. Diazepam concentrations may then decline somewhat, without much change in the concentration of the desmethyl metabolite.

Although benzodiazepines can stimulate liver metabolism in some animals, their induction of the hepatic microsomal enzyme system (CYP enzymes) is of little clinical significance in humans.

Nonbenzodiazepine Hypnotics

Regarding the pharmacokinetics of nonbenzodiazepine hypnotics, no (or only weak) active metabolites exist for the compounds currently available.

Effects on Stages of Sleep

The hypnotic effects of benzodiazepines are thought to derive from the inhibitory effects of the GABAergic system on the raphe and locus coeruleus monoaminergic ascending arousal systems, but this hypothesis may only partially explain their action. Magnocellular regions of the basal forebrain and the preoptic areas have been recognized as important sites for SWS regulation (Szymusiak 1995). Neurons that are selectively active during SWS have been described in these structures, most typically in the ventrolateral preoptic areas (Saper *et al.* 2001; Sherin *et al.* 1996). These neurons contain GABA and galanin, an inhibitory peptide, and project to the main components of the ascending arousal system, such as the raphe and locus coeruleus and brain stem cholinergic nuclei (Saper *et al.* 2001). The ventrolateral preoptic nucleus also sends a dense inhibitory projection to the tuberomammillary histaminergic nucleus, another important wake-promoting system (see Saper *et al.* 2001; Sherin *et al.* 1996). Benzodiazepines may thus indirectly modulate these wake-active monoaminergic neurons to promote their hypnotic effects.

Another important site of action for benzodiazepines may be the suprachiasmatic nucleus (SCN). In SCN-lesioned animals, benzodiazepine administration does not induce sleep (Edgar *et al.* 1993), but the hypnotic effect is restored if the SCN-lesioned animal is sleep deprived before drug administration. Benzodiazepines thus may facilitate the release of a sleep debt accumulated during wakefulness rather than producing de novo sleep (Mignot *et al.* 1992).

The effects of benzodiazepines on sleep architecture are well known. Most benzodiazepines decrease sleep latency (i.e., the amount of time it takes to fall asleep), especially when use is first initiated, and reduce the number of awakenings (Table 44-1). All benzodiazepines increase the time spent in stage 2 sleep. Benzodiazepines also affect the quality of the SWS pattern. Thus, stages 3 and 4 sleep are suppressed and remain so during the period of drug administration. The decrease in stage 4 sleep is accompanied by a reduction in nightmares.

TABLE 44-1. Comparative effects of benzodiazepines and barbiturates on sleep parameters

Parameter	Benzodiazepines	Barbiturates

Note. REM = rapid eye movement sleep; | = increased; | = decreased.

Parameter	**Benzodiazepines**	**Barbiturates**
Total sleep time	| tolerance with short-acting agents	| rapid tolerance
Stage 2, %	|	|
Slow-wave sleep (stages 3 and 4), %	|	| (slight)
REM latency	|	|
REM, %	| (slight)	|
Withdrawal	Rebound insomnia with short-acting agents Carryover effectiveness with long-acting agents REM rebound (slight)	REM rebound Rebound decrease in stage 2 and total sleep time

Note. REM = rapid eye movement sleep; | = increased; | = decreased.

Most benzodiazepines increase REM latency. The time spent in REM sleep is usually shortened; however, the reduction in percentage of REM sleep is minimal because the number of cycles of REM sleep usually increases late in the sleep time. Despite the shortening of SWS and REM sleep, the net effect of benzodiazepines is usually an increase in total sleep time, so that the person feels that the quality of sleep has improved. Furthermore, the hypnotic effect is greatest in subjects with the shortest baseline total sleep time.

If the benzodiazepine is discontinued after 3-4 weeks of nightly use, a rebound in the amount and density of REM sleep and SWS may occur.

However, this is not a consistent finding.

Because long-acting benzodiazepine hypnotics impair daytime performance and increase the risk of falls in older adults, several shorter-acting benzodiazepines are the preferred choice for them (see section "General Considerations in the Pharmacological Treatment of Insomnia" later in this chapter). However, it has been found that short-acting benzodiazepines can induce rebound insomnia (a worsening of sleep difficulty beyond baseline levels on discontinuation of a hypnotic) (Kales *et al.* 1979), rebound anxiety, anterograde amnesia, and even paradoxical rage (Figure 44-7). Many other factors, such as the subtype of insomnia being treated and the dosage and duration of treatment, are also important in explaining the occurrence of these specific side effects, which also may occur with longer-acting benzodiazepines. Nevertheless, enthusiasm for shorter-acting compounds has been tempered by the discovery of these adverse effects.

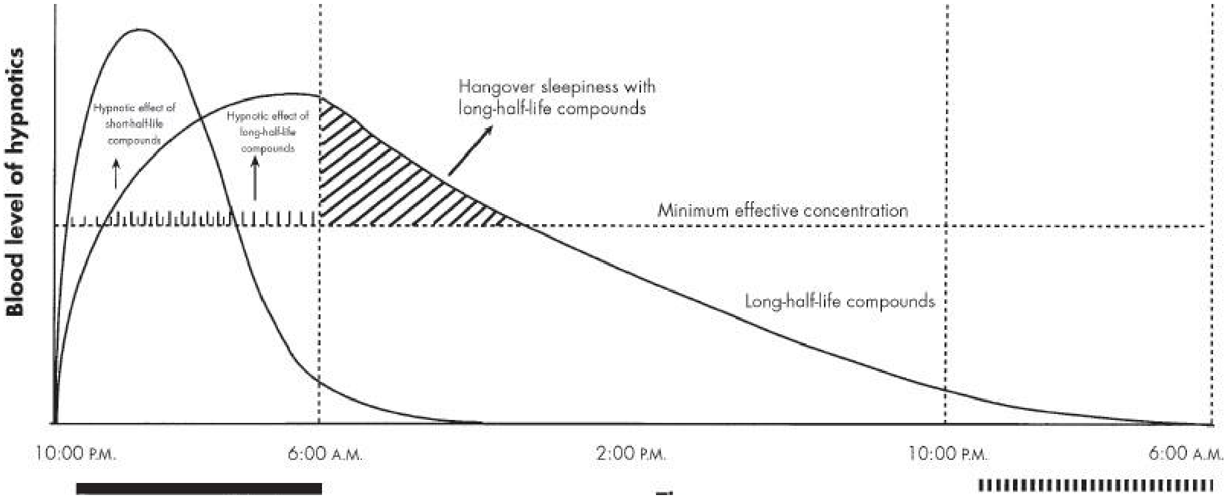

FIGURE 44-7. Duration of action of hypnotics and hangover and rebound insomnia effects.

Hypnotics with long half-lives may impair daytime performance the day after drug administration, whereas short-acting compounds may induce rebound insomnia on discontinuation.

Indications and Efficacy

Benzodiazepines are the drug treatment of choice in the management of anxiety, insomnia, and stress-related conditions. Although none of the currently available compounds has any significant advantage over the others, some drugs can be selected to match the patient's symptom patterns to their pharmacokinetics. If a patient has a persistently high level of anxiety, one of the precursors of desmethyldiazepam, such as diazepam or clorazepate, is most appropriate. Patients with fluctuating anxiety may prefer to take a shorter-acting compound, such as oxazepam or lorazepam, when stressful circumstances occur or are expected.

The indications for nonbenzodiazepine hypnotics are equivalent to those of benzodiazepine hypnotics but may be more specific, depending on the pharmacological properties of each compound.

An ideal hypnotic should induce sleep rapidly without producing sedation the next day. Both flurazepam and nitrazepam have inappropriately long half-lives as hypnotics unless a persistent anxiolytic effect is desired the next day (see Figure 44-7). Even in such situations, diazepam given as a single dose at night may be suitable. Oxazepam penetrates too slowly for a dependable hypnotic effect (slow onset of action). Both lorazepam and temazepam are appropriate treatments for insomnia, but these medications are recommended for short-term use due to withdrawal symptoms (Table 44-2). Triazolam is the shortest-acting hypnotic available. When very small doses of benzodiazepines (which are assumed to have no significant hypnotic action) are administered to patients with insomnia, sleep quality often improves greatly, and usually it is not necessary to prescribe a benzodiazepine at a hypnotic dose as a first-choice treatment.

TABLE 44-2. Pharmacokinetic properties of GABA-enhancing hypnotic compounds most commonly used in the United States

Hypnotic compounds	Usual dose (mg)	T_{max} (hours)[a]	Half-life (hours)[b]	Active metabolites
Benzodiazepines				
Flurazepam (Dalmane)	15-30	0.5-1.0	48-150	*N*-Desalkylflurazepam
Quazepam (Doral)	7.5-15	2	48-120	2-Oxoquazepam, *N*-dealkyl-2-oxoquazepam
Estazolam (ProSom)	1-2	4.9	18-30	1-Oxoestazolam
Lorazepam (Ativan)	2-4	0.8-1.0	10-20	None
Temazepam (Restoril)	15-30	1.5	8-20	None
Triazolam (Halcion)	0.125-0.25	1.3	2-6	None
Nonbenzodiazepines				
Zolpidem (Ambien)	5-10	0.8	1.5-2.4	None
Zopiclone (Imovane in Canada)	3.75-7.5	1.5	5-6	*N*-Oxide zopiclone (weak agonist)
Eszopiclone (Lunesta)	1-3	1	6-9	*S*-Desmethylzopiclone (weak agonist)
Zaleplon (Sonata)	5-20	1.0	1.0-2.5	None

[a] T_{max} is the time required to reach maximal (peak) plasma concentration.

[b] Half-life is the time required by the body to metabolize or inactivate half the amount of a substrate taken.

Benzodiazepines can increase the frequency of apneic episodes and exacerbate oxygen desaturation both in healthy subjects and in subjects with chronic bronchitis (Geddes *et al.* 1976). Although many reports suggest that benzodiazepines are safe for patients with obstructive sleep apnea, some authors disagree, and it seems wise to avoid hypnotics for patients with severe sleep apnea. Another contraindication is myasthenia gravis, a condition in which muscle relaxation with benzodiazepines can exacerbate muscle atonia.

Side Effects and Toxicology

When a benzodiazepine is taken at high dosages, tiredness, drowsiness, and profound feelings of detachment are common but can be minimized by a careful dosage adjustment. Headache, dizziness, ataxia, confusion, and disorientation are less common except in older adults. A marked potentiation of the depressant effect of alcohol occurs. Other less common side effects include weight gain, skin rash, menstrual irregularities, impairment of sexual function, and (very rarely) agranulocytosis.

Although otherwise asymptomatic individuals clearly show mental impairment with benzodiazepines, the situation with anxious patients is more complex. Because anxiety itself interferes with mental performance, alleviation of anxiety may result in improved functioning, which more than compensates for the direct drug-related decrement. The effects in some patients may be complex and unpredictable, even at low dosages.

Tolerance and Dependence

The fact that some patients gradually increase the dosage suggests tolerance, but increases in dosage are sometimes related to particularly stressful crises.

Dependence, both psychological and physical, occurs with benzodiazepines as with other sedative-hypnotics. Abrupt discontinuation results in withdrawal phenomena such as anxiety, agitation, restlessness, and tension, which are usually delayed for several days because of the long half-life of the major metabolite, desmethyldiazepam. Even without an increased dosage, some patients have withdrawal effects. Psychological dependence is also common, based on the high incidence of repeated prescriptions, but it is mild, and the drug-seeking behavior is much less persistent with benzodiazepines than with barbiturates.

Use During Pregnancy and Lactation

Because the safety of benzodiazepines in early pregnancy has not been established, use of these compounds should be avoided unless absolutely necessary. Diazepam is secreted in breast milk and may make the infant sleepy, unresponsive, and slow to feed.

Overdose

The benzodiazepines are very widely prescribed, so it is not surprising that they are used in many suicide attempts. For adults, overdoses of benzodiazepines reportedly are not fatal unless alcohol or other psychotropic drugs are taken simultaneously. Typically, the patient falls asleep but is arousable and wakes after 24-48 hours. Treatment is supportive. A stomach pump is usually more punitive than therapeutic, and dialysis is usually ineffective because of high plasma binding.

Barbiturates

History and Discovery

Barbital, one of the derivatives of barbituric acid, was introduced in 1903 and soon became extremely popular in clinical medicine because of its sleep-inducing and anxiolytic effects (Maynert 1965). In 1912, phenobarbital was introduced as a sedative-hypnotic. Since then, more than 2,500 barbiturate analogs have been synthesized, about 50 of which have been made commercially available and only 20 of which remain on the market.

The success of the partial separation of anticonvulsant from sedative-hypnotic properties led to the development of nonsedative anticonvulsants such as phenytoin in the late 1930s and trimethadione in the early 1940s. The success of barbiturates as sedative-hypnotics was largely overshadowed by the discovery of the benzodiazepines in the late 1960s. With pharmacological properties very similar to those of barbiturates, the benzodiazepines have a much safer pharmacological profile. Thus, benzodiazepines have replaced barbiturates in many instances, especially for psychiatric conditions in which suicide is a possibility.

Structure-Activity Relations

Derivatives of barbituric acid, the parent compound of all barbiturates, do not dissolve readily in water but are quite soluble in nonpolar solvents. In general, structural changes that increase liposolubility also decrease these compounds' duration of action, decrease the latency to onset of activity, accelerate metabolic degradation, and often increase hypnotic potency.

Compared with barbituric acid derivatives with methyl groups at position 5, those with large aliphatic groups at this position have greater activity but a shorter duration of action. However, when aliphatic groups have more than seven carbons, they lose their hypnotic activity and tend to exhibit convulsant activity. Methylation of the 1-*N* atom increases liposolubility and shortens duration of action, and desmethylation may increase the duration of action (Rall 1990).

Pharmacological Profile and Mechanism of Action

The main effects of barbiturates are sedation, sleep induction, and anesthesia. Some barbiturates, such as phenobarbital, also have selective anticonvulsant properties. The mechanisms of action of barbiturates are complex and still not fully understood. Nonanesthetic dosages of barbiturates generally suppress polysynaptic responses. Pertinent to their sedative-hypnotic effects is the fact that the mesencephalic reticular activating system is extremely sensitive to these drugs (Killam 1962). The synaptic site of inhibition is either postsynaptic (e.g., at the level of cortical and cerebellar pyramidal cells and in the cuneate nucleus, substantia nigra, and thalamus relay neurons) or presynaptic (e.g., in the spinal cord). This inhibition occurs only at synapses where physiological inhibition is GABAergic but not glycinergic or monoaminergic. Thus, barbiturates, like benzodiazepines, specifically potentiate GABA-mediated inhibitory processes in the brain. However, it remains unclear whether all of the effects of barbiturates are entirely mediated by GABAergic mechanisms.

Barbiturates do not displace benzodiazepines from their binding sites; instead, barbiturates enhance benzodiazepine binding by increasing the affinity of the receptor for benzodiazepines (Leeb-Lundberg *et al.* 1980). They also enhance the binding of GABA and its agonists to specific binding sites (Asano and Ogasawara 1981). These enhancement effects are almost completely dependent on the presence of chloride or other anions that are known to permeate the chloride channels associated with the GABA receptor complex, and they are competitively antagonized by picrotoxin (a convulsant) (Olsen *et al.* 1978).

The molecular correlations of the barbiturate acting sites on the $GABA_A$ receptor also have been studied. However, neither the sequences involved in the binding of GABA and other direct receptor agonists nor the sequence involved in the action of benzodiazepines is of vital importance to barbiturate function (Amin and Weiss 1993). Whereas some earlier reports suggested that the b subunit alone may form a site for barbiturates (Sanna *et al.* 1995), recent studies attempting to identify structural characteristics and binding sites have found that barbiturates bind to the $GABA_A$ receptor at multiple homologous transmembrane pockets at the subunit interfaces (Chiara *et al.* 2013). Although there is still much to be learned, new molecular experimental approaches hold great promise for resolving the most important pharmacological questions regarding which molecular species are important for the anticonvulsant, sedative, anesthetic, and toxic actions of the barbiturates.

Pharmacokinetics and Disposition

For hypnotic use, barbiturates usually are administered orally. Barbiturates are rapidly absorbed in the stomach, and their absorption decreases when the stomach is full.

Barbiturates are metabolized mainly in the liver. Oxidation of the larger of the two side chains at position 5 is a major catabolic pathway. It generally produces inactive polar metabolites that are rapidly excreted in the urine (Rall 1990). Changes in liver function can markedly alter the metabolic rate. Chronic administration leads to pharmacokinetic tolerance, even when low or infrequent doses of barbiturates are used (see subsection "Drug-Drug Interactions" later in this section).

In general, liposolubility decreases both latency to onset of action and duration of action. Thiopental, for example, enters the CNS quickly and is used to rapidly induce anesthesia; barbitone crosses into the brain so slowly that it is inappropriate as a hypnotic drug.

Effects on Stages of Sleep

Barbiturates decrease sleep latency; however, they also slightly increase fast electroencephalogram activity during sleep. Barbiturates decrease body movements during sleep. Stage 2 sleep increases, whereas stage 3 and stage 4 SWS generally decrease (except for some patients who have anxiety and patients who are addicted to barbiturates; see Table 44-1). REM sleep latency is prolonged, and both the total time spent in REM sleep and the number of REM cycles are diminished. With repeated nighttime administration (i.e., taking a new dose before elimination of the previous dose) of barbiturates, drug tolerance to the effects on sleep occurs in a few days. Discontinuation of barbiturates may lead to insomnia and to disrupted sleep patterns (with a decrease in stage 2 sleep and increases in REM sleep) (Kay *et al.* 1976).

Indications and Efficacy

Although clinical trials have shown that the barbiturates have sedative and hypnotic properties, barbiturates generally compare poorly with benzodiazepines. The patient feels "drugged" the next day, and there is always the risk of fatal overdose because of the depressant effect on respiration. The therapeutic dosage of barbiturates may cause fatal respiratory depression in patients with sleep apnea; therefore, barbiturate use is contraindicated for such patients. Because of these risks, many clinicians have stopped using barbiturates as hypnotics and sedatives (one exception is in the treatment of severe psychomotor excitation) and prescribe them only as anticonvulsants.

Barbiturates also have been administered intravenously to facilitate patient interviews (i.e., amobarbital interview).

Because they enhance porphyrin synthesis, barbiturates are contraindicated for patients with porphyria. Liver function should be checked before and during drug administration. Liver dysfunction can significantly prolong the sedative effects of these drugs and may lead to fatal overdose.

Side Effects and Toxicology

For many patients who are prescribed barbiturates, it is difficult to control symptoms without causing oversedation. Patients typically oscillate between anxiety and torpor. Mental performance is often impaired, and patients should not drive or operate dangerous machinery.

Patients whose conditions have been stabilized for years with barbiturates must be considered drug dependent. Withdrawal leads to anxiety, agitation, trembling, and, frequently, convulsions. Substitution with a benzodiazepine that can be withdrawn more easily later is often successful.

Tolerance and Dependence

Tolerance to barbiturates occurs rapidly and is a result of both pharmacokinetic factors (e.g., liver enzyme induction) and pharmacodynamic factors (e.g., neuronal adaptation to chronic drug administration). Cross-tolerance develops to alcohol, gas anesthetics, and other sedatives, including benzodiazepines.

Psychological dependence (i.e., drug-seeking behavior) is common. Patients typically visit several physicians to obtain more barbiturates. Physical dependence may be induced by a dosage of 500 mg/day. Intoxication may occur, as evidenced by impaired mental functioning, emotional instability, and neurological signs. Abrupt discontinuation after high dosages is likely to induce convulsions and delirium. After normal dosages, withdrawal phenomena include anxiety, insomnia, restlessness, agitation, tremor, muscle twitching, nausea and vomiting, orthostatic hypotension, and weight loss.

Overdose

An overdose of barbiturates leads to fatal respiratory and cardiovascular depression. Suicide attempts often involve overdoses of barbiturates, taken either alone or in combination with alcohol or other psychotropic drugs, particularly tricyclic antidepressants. These suicide attempts, unfortunately, are often successful. Depending on local factors such as proximity to a hospital and expertise of staff in intensive emergency care, death occurs in 0.5%-10% of these cases. Severe poisoning results at 10 times the usual hypnotic dosage, and twice that amount may be fatal.

Drug-Drug Interactions

Barbiturates used with other CNS depressants can cause severe depression. Ethanol is the drug most frequently used in combination with barbiturates, and interactions with antihistaminic compounds are also common. Monoamine oxidase inhibitors and methylphenidate also increase the CNS depressant effect of barbiturates.

Barbiturates may increase the activity of hepatic CYP enzymes twofold to threefold. Clinically, this change is particularly important for patients who are also receiving metabolic competitors such as warfarin or digitoxin, for which careful control of plasma concentrations is vital (Rall 1990).

Other Sedative-Hypnotic Compounds

Table 44-3 summarizes the pharmacological properties of some of the newer classes of hypnotic compounds, including orexin (hypocretin) receptor antagonists, melatonin receptor agonists, and sedative antidepressants with H_1 antagonism.

TABLE 44-3. **Pharmacokinetic properties of newer classes of hypnotic compounds most commonly used in the United States**

Hypnotic compounds	Mechanisms	Usual dose (mg)	T_{max} (hours)^a	Half-life (hours)^b	Active metabolites
Melatonergics					
Melatonin (Circadin^c)	Melatonin receptor agonist	0.5-5.0 (2^c)	0.83 (1.6-2.6^c)	0.75 (3.5-4.0^c)	N^1-acetyl-N^2-formyl-5-methoxykynuramine (AFMK), N^1-acetyl-5-methoxykynuramine (AMK)
Ramelteon (Rozerem)	Melatonin receptor agonist	8	0.75	1.0-2.6	M-II
Tasimelteon (Hetlioz)	Melatonin receptor agonist	20	2	1.3-3.7	None
Orexin receptor antagonists					
Suvorexant (Belsomra)	Orexin receptor antagonist	10-20	2	12	None
Lemborexant (Dayvigo)	Orexin receptor antagonist	5-10	1-3	17-19	M10 (weak antagonist)
Antidepressant sedatives					
Doxepin (Silenor)	H_1 receptor antagonist	3-6	3.5	15.3	*N*-desmethyldoxepin

5-HT_{2C} = 5-hydroxytryptamine (serotonin) type 2C receptor; H_1 = histamine type 1 receptor.

[a] T_{max} is the time required to reach maximal (peak) plasma concentration.

[b] Half-life is the time required by the body to metabolize or inactivate half the amount of a substrate taken.

[c] Prolonged-release tablet.

Hypnotic compounds	Mechanisms	Usual dose (mg)	T_{max} (hours)[a]	Half-life (hours)[b]	Active metabolites
Agomelatine (Valdoxan in EU)	Melatonin receptor agonist; 5-HT_{2C} receptor antagonist	25-50	0.5-4.0	1-2	None

5-HT_{2C} = 5-hydroxytryptamine (serotonin) type 2C receptor; H_1 = histamine type 1 receptor.

[a] T_{max} is the time required to reach maximal (peak) plasma concentration.

[b] Half-life is the time required by the body to metabolize or inactivate half the amount of a substrate taken.

[c] Prolonged-release tablet.

Alcohol-Type Hypnotics

The alcohol-type hypnotics include the chloral derivatives, of which chloral hydrate (0.5-1.0 g), clomethiazole (192 or 384 mg), and ethchlorvynol (0.5-1.0 g) are still used occasionally by older adults. Chloral hydrate is metabolized to another active sedative-hypnotic, trichloroethanol. These drugs have short half-lives (~ 4-6 hours) and decrease sleep latency and number of awakenings; SWS is slightly depressed, but overall REM sleep time is largely unaffected. Chloral hydrate and its metabolite have an unpleasant taste and frequently cause epigastric distress and nausea. Undesirable side effects include light-headedness, ataxia, and nightmares. Chronic use of these drugs can lead to tolerance and occasionally to physical dependence. As with barbiturates, overdose can lead to respiratory and cardiovascular depression, and therapeutic use of these drugs has largely been superseded by the use of benzodiazepines.

Gamma-Hydroxybutyrate/Sodium Oxybate

g-Hydroxybutyrate (GHB) is a hypnotic agent that has been used mostly in the treatment of insomnia for narcoleptic patients (Scrima *et al.* 1990). A small amount of GHB naturally also exists in the CNS (Bessman and

Fishbein 1963). The drug is rarely used in other indications and is often abused. GHB was classified as a Schedule I controlled substance in March 2000 in the United States, but in July 2002, the drug's sodium salt form, sodium oxybate (Xyrem), was approved by the FDA for the treatment of narcolepsy, and a combination calcium, magnesium, potassium, and sodium oxybate formulation (Xywav) was approved in 2021. Nighttime administration of GHB (20-40 mg/kg) reduces excessive daytime sleepiness associated with narcolepsy. The compound promotes SWS and REM sleep (Lapierre *et al.* 1990), but its effects on sleep architecture are short-lasting, and repeated administration usually is necessary during the night. GHB also is used for the treatment of cataplexy in narcolepsy, although the mechanisms of GHB's effect on cataplexy remain unknown.

The physiological significance of a brain GHB signaling pathway and the detailed mechanisms of many actions of exogenous GHB remain unclear. Exogenously administered GHB induces a wide range of neuropharmacological actions, including sedation, memory impairment, an increase in sleep, seizures, dependence or abuse, and coma (Wong *et al.* 2004). GHB has long been known to have an effect on dopamine systems in the brain and probably inhibits dopamine release (Vayer *et al.* 1987).

Most of these actions of exogenous GHB have been shown to be mediated, either fully or in part, by GABA$_{\text{B}}$ receptors (Castelli *et al.* 2004; Maitre 1997; Wong *et al.* 2004). In 2003, the cloning of a putative GHB receptor was reported (Andriamampandry *et al.* 2003).

Despite these findings, the physiological significance of a brain GHB signaling pathway is still unknown, and there is an urgent need for a well-validated functional assay for GHB receptors. Moreover, as GHB can also be metabolized to GABA, it remains to be seen whether the many GABA$_{\text{B}}$ receptor-mediated actions of GHB are caused by GHB itself acting directly on GABA$_{\text{B}}$ receptors or by a GHB-derived GABA pool (or both) (Wong *et al.* 2004).

Antihistamines

Antihistamines such as promethazine (25-50 mg), diphenhydramine (25-50 mg), and doxylamine (25 mg) are sometimes prescribed as sleep inducers. They decrease sleep latency but do not increase total sleep time (see Reite *et al.* 1997). These compounds are especially useful for patients who cannot sleep well because of acute allergic reactions or itching. Because sedative antihistamines lack abuse potential, they also may be a good choice for people with substance use disorders. However, rapid tolerance is a problem.

In April 2008, doxepin hydrochloride (marketed under the trade name Silenor), a tricyclic antidepressant with histamine$_1$ (H_1) receptor antagonism, received FDA approval for the treatment of insomnia (see Table 44-3). Doxepin (as Sinequan, 3 mg and 6 mg) reduces wake after sleep onset and prolongs total sleep time (Markov and Doghramji 2010).

Low-dose doxepin has a terminal half-life of 15.3 hours, and the median time to peak plasma concentration (T_{max}) of doxepin 6 mg is 3.5 hours (Atkin *et al.* 2018). The *N*-desmethyl metabolite of doxepin, *N*-desmethyldoxepin, is pharmacologically active (Kemp *et al.* 1985). Several other selective H_1 receptor blockers and H_1 receptor reverse agonists are under development for use as hypnotics.

GABA Reuptake Receptor Inhibitor

Tiagabine is a GABA reuptake receptor (GAT-1) inhibitor that allows increased GABA concentration at the synaptic level of the CNS (Mathias *et al.* 2001). Tiagabine has been shown to prolong GABA-mediated inhibitory postsynaptic potentials. Tiagabine is in the class of medications called anticonvulsants and is used in combination with other medications to treat partial seizures. Tiagabine (4-16 mg) has been shown to produce a dose-dependent increase in SWS in older adults and patients with primary insomnia (Walsh *et al.* 2006). Doses as low as 10 mg increase the power density of slow electroencephalographic oscillations and also increase the percentage of SWS from 15% to 24% (Mathias *et al.* 2001). Tiagabine, originally approved by the FDA in 1997 as an adjunctive treatment for partial seizures, may be a compound of interest for sleep disorders; however, it has not received FDA approval for the treatment of insomnia.

Melatonin and Melatonin Receptor Agonists

Melatonin

Melatonin is a neurohormone produced by the pineal gland during the dark phase of the day-night cycle. The terminal half-life of melatonin is 45 minutes, and its median T_{max} is 50 minutes (Harpsoe *et al.* 2015). Melatonin has active metabolites such as *N*1-acetyl-*N*2-formyl-5-methoxykynuramine and *N*1-acetyl-5-methoxykynuramine (Hardeland and Pandi-Perumal 2005). In animals, melatonin has been implicated in the circadian regulation of sleep and in the seasonal control of reproduction. Studies suggest that melatonin administration may have some therapeutic effects in various disturbances of circadian rhythmicity, such as those related to jet lag (Arendt *et al.* 1987), shift work (Folkard *et al.* 1993), non-24-hour sleep-wake cycle in blind people (Arendt *et al.* 1988), and delayed sleep phase insomnia (Dahlitz *et al.* 1991), with few side effects (e.g., headaches or nausea). High dosages of melatonin (3-100 mg), which increase serum melatonin levels far beyond the normal nocturnal range, have been suggested to produce hypnotic effects in humans (Dollins *et al.* 1994). Lower and more physiological dosages of melatonin (e.g., 0.3 mg) might also be active (Zhdanova *et al.* 2001).

In humans, the production of melatonin during the dark period declines with age; this effect parallels declines in sleep quantity and quality (van Coevorden *et al.* 1991), especially in older adults with insomnia (Haimov *et al.* 1994; Mishima *et al.* 2001). These findings appear to suggest that deficiencies in nocturnal melatonin secretion might contribute to disrupted sleep in older adults; thus, melatonin may be particularly beneficial for insomnia in this population. Indeed, some studies reported favorable effects with supplementary administration of melatonin for older adults with disturbances in sleep maintenance (Garfinkel *et al.* 1995; Haimov *et al.* 1995). However, several studies reported contradictory findings indicating no significant relation between physiological melatonin secretion levels and sleep maintenance parameters (Hughes *et al.* 1998; Lushington *et al.* 1998; Youngstedt *et al.* 1998; Zeitzer *et al.* 1999) and no significant therapeutic effect of melatonin replacement on sleep maintenance in older adults with insomnia (Hughes *et al.* 1998).

One of the difficulties in establishing the therapeutic efficacy of melatonin is its short half-life (~ 45 minutes) (Harpsoe *et al.* 2015). Bedtime melatonin administration (1-3 mg) reduces sleep latency but has few objective effects on sleep architecture. It is also unclear whether the hypnotic effect from a physiological or pharmacological dose represents a direct effect on sleep, an indirect effect on circadian timing that subsequently gates the release of sleep, or both. Finally, very few double-blind, placebo-controlled studies have been done, and most current reports are confounded by strong placebo effects in the context of a melatonin fad. Melatonin might be an effective hypnotic in some indications, but better-controlled studies are needed to establish its efficacy in specific indications. The purity of products sold as health supplements is also a problem, and the long-term effects of melatonin administration in humans are unknown.

Circadin is a prolonged-release formulation of melatonin, designed to mimic the release pattern of endogenous melatonin by releasing melatonin gradually over 8-10 hours (Laudon and Frydman-Marom 2014), because the half-life of melatonin taken orally is very short (~ 45 minutes). Circadin has been used in multiple clinical trials, showing statistically significant and clinically meaningful efficacy in insomnia parameters (Laudon and Frydman-Marom 2014; Lemoine *et al.* 2007; Wade *et al.* 2010). Its use as a prescribed drug has been approved in some countries (e.g., Australia, New Zealand), but not in the United States. Circadin is fully absorbed, but bioavailability is only about 15% because of its high first-pass hepatic degradation, primarily through CYP1A2. After oral ingestion, maximal melatonin concentrations in the blood are attained after 0.75 hour in fasting and 3 hours in nonfasting states. Circadin is eliminated mainly as sulfated and glucuronide conjugates after biotransformation in the liver and only partly (2%) as unchanged melatonin. The terminal half-life of Circadin is 3.5-4 hours, and T_{max} requires 1.6 hours (fasting) to 2.6 hours (nonfasting) to occur (New Zealand Medicines and Medical Devices Safety Authority 2011).

Melatonin Receptor Agonists

There are at least three subtypes of melatonin receptors with high (MT_1 or MT_{1a}) and low (MT_2 or MT_{1b} and MT_3 or MT_{1c}) affinities for this ligand (Dubocovich 1995; Morgan *et al.* 1994; Reppert *et al.* 1994, 1995). The localization of the MT_1 receptor in the SCN, median eminence, and retina in humans and rodents suggests that this receptor is essential for circadian regulation and reproduction, whereas the MT_2 receptor is localized mainly in the retina. Melatonin receptors in the retina probably play an important role in retinal physiology, including circadian regulation (Sengupta *et al.* 2011) and photopigment disc shedding (Besharse and Dunis 1983).

Ramelteon (8 mg), a melatonin receptor agonist with both high affinity for melatonin MT_1 and MT_2 receptors and low affinity for the MT_3 receptor and with a longer half-life than melatonin, was approved by the FDA in July 2005 for the treatment of insomnia characterized by difficulty with sleep onset (see Kuriyama *et al.* 2014; Takeda Pharmaceuticals America, Inc. 2010). The terminal half-life of ramelteon is 1-2.6 hours, and its median T_{max} is 45 minutes (Zammit 2007). Ramelteon is metabolized primarily to the active metabolite M-II (Nishiyama *et al.* 2014). Ramelteon does not show any appreciable binding to $GABA_A$ receptors, which are associated with anxiolytic, myorelaxant, and amnesic effects. Ramelteon has not been demonstrated to produce dependence and has shown no potential for abuse, and the withdrawal and rebound insomnia typically seen with other GABA modulators do not appear to be present.

Animal studies demonstrated that the sleep-enhancing effects of ramelteon are not associated with reductions in REM sleep (Miyamoto *et al.* 2004). Ramelteon is currently the only nonscheduled prescription drug for the treatment of insomnia available in the United States. It has no appreciable affinity for receptors that bind neuropeptides, cytokines, serotonin, dopamine, norepinephrine, acetylcholine, and opiates. It also does not interfere with the activity of any known enzymes in standard panels. The activity of ramelteon at the MT_1 and MT_2 receptors, especially those in the SCN, is believed to contribute to its sleep-promoting properties, as these receptors, acted upon by endogenous melatonin, are thought to be involved in maintenance of the circadian rhythm underlying the normal sleep-wake cycle.

The activity of ramelteon is similar to the biological action of melatonin. No published studies have reported comparative data on whether ramelteon is more or less safe or effective than melatonin, a much less expensive drug widely available in the United States without a prescription.

Recent studies have reported findings suggesting that melatonin (0.5 mg) or ramelteon (8 mg) can prevent delirium in older adults (Al-Aama *et al.* 2011; Hatta *et al.* 2014). Although significant decline in melatonin levels during aging has been reported by many investigators (Srinivasan *et al.* 2006), modes of action for preventing delirium in older adults are not known.

Another MT_1/MT_2 receptor agonist, tasimelteon (Rajaratnam *et al.* 2009), was approved by the FDA in January 2014 for the treatment of non-24-hour sleep-wake disorder (N24HSWD) in totally blind people (Vanda Pharmaceuticals Inc. 2014; see also Sack *et al.* 1991). The terminal half-life of tasimelteon is 1.3-3.7 hours, and the median T_{max} is 2 hours (Bonacci *et al.* 2015). When taken as a treatment for N24HSWD, similar to melatonin, the patient may experience improved sleep timing. The metabolism of tasimelteon consists primarily of oxidation at multiple sites and oxidative dealkylation. CYP1A2 and CYP3A4 are the major isozymes involved in the metabolism of tasimelteon. Phenolic glucuronidation is the major phase II metabolic route. Major metabolites had 13-fold or less binding affinity at melatonin receptors compared with tasimelteon. Therefore, the metabolites do not contribute to its efficacy. Tasimelteon has been developed for the treatment of circadian rhythm sleep disorders (Nishimon *et al.* 2019). Approximately 55%-70% of totally blind patients are thought to have nonentrained rhythms, and if they report periodic difficulties with sleep or daytime alertness they are diagnosed as having N24HSWD ("free running") (Nishimon *et al.* 2019). Phase II and III studies have been conducted in transient insomnia associated with shifted sleep and wake time (Hardeland 2009). In the Phase II study, tasimelteon reduced sleep latency, increased sleep efficiency compared with placebo, and dose-dependently advanced plasma melatonin rhythm. In the Phase III study, tasimelteon improved sleep latency, sleep efficiency, and wake after sleep onset. The frequency of adverse events in both studies was comparable to that of placebo (Mulchahey *et al.* 2004).

Agomelatine is a melatonin MT_1 and MT_2 receptor agonist and a weak serotonin$_{2C}$ (5-HT_{2C}) antagonist. In addition to its antidepressant effects, agomelatine improved sleep quality and reduced waking after sleep onset in depressed patients (Taylor *et al.* 2014). Whereas the sleep-promoting effects of agomelatine can clearly be ascribed to its melatonergic activity, the antidepressant function has been ascribed to 5-HT_{2C} receptor antagonism. However, because of agomelatine's short half-life and low 5-HT_{2C} affinity, it is disputed to what extent the 5-HT_{2C} antagonism contributes to its therapeutic effect (Millan *et al.* 2011). After ingestion, agomelatine is rapidly and well absorbed (80%) irrespective of food intake. The peak plasma levels are reached in 0.5-4 hours, and plasma half-life is short (1-2 hours) (De Berardis *et al.* 2015). It is highly protein bound (> 95%) and is metabolized in the liver, primarily through CYP1A2, to form inactive metabolites that are mainly (80%) excreted in the urine. A major metabolite, 3-hydroxy-7-desmethyl-agomelatine, has low affinity for MT_1, MT_2, and 5-HT_{2C} receptors (Dolder *et al.* 2008). Because of the antidepressant effects of agomelatine, this drug may also be used for insomnia associated with depressive symptoms in older adults and is well tolerated in depressed patients older than 65 years (Heun *et al.* 2013).

Melatonin receptor agonists may be useful for patients who experience insomnia due to shift work or jet lag, as well as for delayed sleep phase syndrome or advanced sleep phase syndrome, as beneficial effects of melatonin were reported in these conditions.

Orexin (Hypocretin) Receptor Antagonists

Orexin A (or hypocretin 1) and orexin B (or hypocretin 2) are newly discovered hypothalamic neuropeptides that play critical roles in the promotion and maintenance of wakefulness and in the pathophysiology of narcolepsy with cataplexy (Nishino 2011; Sakurai *et al.* 1998). In humans, chronic loss of orexin neurons is associated with narcolepsy with cataplexy (i.e., type 1 narcolepsy, as defined by the *International Classification of Sleep Disorders*, 3rd Edition [ICSD-3] [American Academy of Sleep Medicine 2014]). Orexin neurons are presumed to be active during wakefulness and reduce activities during sleep, and two G-protein-coupled receptors for orexin peptides (orexin receptor 1 and orexin receptor 2) have been identified (Nishino 2011; Sakurai *et al.* 1998).

Although attempts to treat human narcolepsy with orexin receptor agonists are still in progress, suvorexant, an orally active dual orexin receptor antagonist, was recently developed and in 2014 was approved for the treatment of adult patients with insomnia characterized by difficulties with sleep onset or sleep maintenance (see Winrow *et al.* 2011; Yang 2014; also see Merck and Co. 2014). The recommended dosage is 10 mg (a maximum of 20 mg once daily), to be taken orally once per night, within 30 minutes of going to bed and with at least 7 hours remaining until the planned waking time.

Suvorexant 15 or 20 mg once daily generally improved sleep maintenance and sleep onset (Jacobson *et al.* 2014). A significantly greater improvement relative to placebo was seen with suvorexant 15 or 20 mg once daily in most objective endpoints at 1 night, 1 month, and 3 months (Jacobson *et al.* 2014). Suvorexant is contraindicated in people diagnosed with narcolepsy, since the consequences of taking orexin receptor antagonists in type 1 (hypocretin deficient) and type 2 (hypocretin nondeficient) narcolepsy are unpredictable (Merck and Co. 2014). Suvorexant is not recommended for patients with liver impairment or for those who are also taking medications that strongly inhibit the liver enzyme CYP3A, such as itraconazole, lopinavir/ritonavir, clarithromycin, ritonavir, ketoconazole, indinavir/ritonavir, or conivaptan (Merck and Co. 2014).

The drug is well tolerated, but adverse effects include sleepiness and fatigue the next day and problems with driving, as well as unusual dreams

(Merck and Co. 2014), and sleep paralysis and hypnagogic/hypnopompic hallucinations may occur with its use. The median T_{max} of suvorexant is 2 hours (in fasting condition), and high-fat food ingestion can delay T_{max} (Cada *et al.* 2015). For suvorexant 10 mg, the mean absolute bioavailability is 82%. Administration of suvorexant with a high-fat meal had no clinical effect on systemic drug exposure but delayed T_{max} by 1.5 hours. Steady state is achieved within 3 days. Suvorexant is metabolized primarily by CYP3A, with a minor contribution by CYP2C19 (Merck and Co. 2014). The main circulating compounds are the unchanged drug and a hydroxyl metabolite, which is not expected to be pharmacologically active. Suvorexant is eliminated primarily in the feces, with recovery of

66% of a radiolabeled dose in the feces and 23% in the urine. The mean elimination half-life of suvorexant is 12 hours (Cada *et al.* 2015).

Concomitant use of suvorexant with other CNS depressant drugs (e.g., benzodiazepines, opioids, tricyclic antidepressants) may result in potentially additive effects; dosage adjustments in either or both drugs may be necessary (Merck and Co. 2014).

Efficacy of suvorexant in delirium prevention was reported in several randomized clinical trials in the ICU or acute care settings (Hatta *et al.* 2017). A recent study has also examined the effects of suvorexant on delirium prevention in everyday clinical settings in a comparison of 84 suvorexant users and 615 suvorexant nonusers (Izuhara *et al.* 2020). Delirium prevalence was significantly lower in suvorexant users than in nonusers (17.9% vs. 32.4%, respectively; $P = 0.007$). Cox regression analysis revealed a significantly lower hazard ratio (0.472; 95% CI: 0.268-0.832; $P = 0.009$) of delirium in suvorexant users than in nonusers. Trazodone also had a preventive effect on delirium (hazard ratio, 0.345; 95% CI: 0.149-0.802; $P = 0.013$).

A study showed that the risk of falls also exists for suvorexant but not ramelteon (Ishibashi *et al.* 2020), and thus it is necessary to carefully prescribe hypnotic drugs under appropriate assessment.

Lemborexant, another dual orexin receptor (OXR) antagonist, has been approved for the treatment of insomnia disorders, and drugs with a distinctive profile (daridorexant) or orexin-2 receptor selectivity (seltorexant) are in development.

In vitro, lemborexant acts as a competitive antagonist at OXR1 and OXR2, with respective IC_{50} values of 6.1 nmol/L and 2.6 nmol/L (Scott 2020; Yoshida *et al.* 2015). The T_{max} ranged from approximately 1 to 3 hours, and the mean effective half-life was 17 hours for 5 mg and 19 hours for 10 mg (Landry *et al.* 2021). A major metabolite of lemborexant (M10) binds with comparable affinity to the parent drug to OXR1 and OXR2 (IC_{50}, 4.2 and 2.9 nmol/L). In December 2019, lemborexant was approved in the United States for the treatment of adults with insomnia characterized by difficulties with sleep onset or sleep maintenance. It is also being investigated for the treatment of irregular sleep-wake rhythm disorder associated with mild to moderate Alzheimer's disease.

Lemborexant improves sleep onset and sleep maintenance for patients with insomnia (Scott 2020). The recommended starting dosage of lemborexant is 5 mg taken once daily immediately before bed. The dosage may be increased to 10 mg if needed; however, patients older than 65 years should be limited to 5 mg once daily. Lemborexant should be taken only if the patient has at least 7 hours to devote to sleep at night. The effectiveness of lemborexant is decreased if it is taken with food, particularly for sleep onset. Lemborexant has been compared with placebo and zolpidem for sleep onset and maintenance in two randomized, double-blind, placebo-controlled studies that included approximately 800 adults (Murphy *et al.* 2017; Yardley *et al.* 2021). It has been shown to improve objective and subjective sleep measures (Murphy *et al.* 2017; Rosenberg *et al.* 2019; Yardley *et al.* 2021). Effects are seen within 1 week and are maintained for at least 12 months; they include faster sleep onset and decreased nighttime awakenings. After 12 months of nightly treatment, patients fell asleep an average of 26 minutes faster with either dosage of lemborexant from a baseline delay of about 1 hour. Lemborexant delays the time to first awakening by about 43 minutes (Yardley *et al.* 2021). In adults older than 55 years, lemborexant decreases time to sleep onset by about 20 minutes, compared with 7.5 minutes with zolpidem extended release ($P < 0.001$). Lemborexant shows a modest improvement over zolpidem in waking after sleep onset, providing an additional 7-9 minutes of sleep before first awakening (Rosenberg *et al.* 2019). Lemborexant has not been studied in shift workers or patients with jet lag.

A meta-analysis examined differences between lemborexant, suvorexant, and zolpidem in efficacy and safety outcomes for treating patients with insomnia (Kishi *et al.* 2020). Primary outcomes were subjective time to sleep onset, subjective total sleep time, and subjective wake after sleep onset at week 1. Four double-blind, randomized controlled trials were identified ($N = 3,237$; mean age 58.0 years). The treatment arm consisted of lemborexant 10 mg/day ($n = 592$), lemborexant 5 mg/day ($n = 589$), suvorexant 20/15 mg/day ($n = 493$), zolpidem tartrate extended release 6.25 mg/day ($n = 263$), and placebo ($n = 1,300$). All active treatments outperformed placebo regarding subjective time to sleep onset at week 1, subjective total sleep time at week 1, and subjective wake after sleep onset at week 1. Although no significant differences were found in discontinuation due to adverse events between each active drug and placebo, lemborexant 10 mg/day and suvorexant 20/15 mg/day were associated with greater daytime somnolence compared with placebo. Lemborexant 10 mg/day had the largest effect size compared with placebo for all primary outcomes, although with a risk of somnolence.

General Considerations in the Pharmacological Treatment of Insomnia

The ICSD is the classification system most commonly used by sleep medicine specialists. The first edition was published in 1990, and the ICSD was subsequently revised in 2005 (ICSD-2) and 2014 (ICSD-3). The sleep disorder chapter in DSM-5 (American Psychiatric Association 2013) also classifies sleep disorders in the same manner as ICSD-3 (American Academy of Sleep Medicine 2014).

Insomnia is a subjective complaint of insufficient, inadequate, or nonrestorative sleep (Buysse and Reynolds 1990). ICSD-3 defines *insomnia* as "a persistent difficulty with sleep initiation, duration, consolidation, or quality that occurs despite adequate opportunity and circumstances for sleep and results in some form of daytime impairment" (American Academy of Sleep Medicine 2014). Inadequate sleep causes disturbances in daytime functioning, such as fatigue, mood problems, and impaired performance.

Insomnia is a common symptom. Estimates of its prevalence depend on the definition criteria used and the population studied. As a result of these differences in case definition, prevalence estimates have varied widely, from 10% to 40% (Mai and Buysse 2008), but tend to average about 30% for insomnia and 5%-10% for specific insomnia disorders at (Roth 2007). The current use of hypnotics in the general population is estimated to range between 3.5% and 11.7% (Mellinger *et al.* 1985; Ohayon and Caulet 1996; Ohayon *et al.* 1998; Quera-Salva *et al.* 1991).

Insomnia is a symptom that must be explored clinically before treatment is initiated. Sleep disturbances often indicate a larger psychiatric problem, such as depression. As mentioned earlier, insomnia is a common complaint in older populations, especially in institutional settings. In some cases, environmental factors (e.g., noise) or other sleep disorders (e.g., periodic leg movements, sleep apneas, parasomnias) may be involved.

The older classifications, ICSD-2 and DSM-IV (American Psychiatric Association 1994), considered the sleep disorder "primary insomnia" if it occurred as an independent disorder and "secondary insomnia" when it related to another mental disorder (e.g., depression) or medical condition (e.g., pain). ISCD-3 and DSM-5 pay more attention to coexisting medical conditions in defining sleep disorders (now called sleep-wake disorders), to better emphasize when a person has a sleep disorder warranting independent clinical attention, in addition to any medical and mental disorders that are also present. DSM-5 recognizes that coexisting medical conditions, mental disorders, and sleep disorders (comorbid insomnia) are interactive and bidirectional, and it is not as important to make assumptions about what causes the sleep disorder (Reynolds and O'Hara 2013). That is the reason the diagnosis of primary insomnia has been renamed *insomnia disorder*, in order to avoid the differentiation of primary and secondary insomnia. Insomnia can be transient, lasting a few days or weeks. Or, if it lasts 3 months or more, it can be a chronic disorder, and in such cases it will typically not remit spontaneously. Previous drug developments for insomnia focused on primary insomnia, and clinical trials typically recruited patients with the primary disorder. However, in the majority of cases insomnia is comorbid with other conditions. It has been increasingly recognized in recent years that insomnia increases the risk of hypertension, cardiovascular disease, metabolic disorders, and Alzheimer's dementia, and the presence of these medical conditions exacerbates the insomnia (Roth and Roehrs 2003; Sivertsen *et al.* 2014). The change in the definition of insomnia by ICSD-3 and DSM-5 may also change the approach to insomnia drug development.

Insomnia Classifications Based on Duration

A useful initial approach to a patient with insomnia is to consider the duration of the complaint (acute [transient, short-term] vs. chronic). The duration of insomnia not only suggests its cause but also provides some guidance on how to use hypnotics.

ICSD-3 identifies three distinct types of insomnia: short-term insomnia, chronic insomnia, and other insomnia (when the patient has insomnia symptoms but does not meet criteria for the other two types of insomnia). Previous editions had subclassified chronic insomnia into primary and comorbid types, but these were eliminated in ICSD-3 because the subclassifications did not improve diagnostic accuracy.

Chronic Insomnia Disorder

ICSD-3 consolidates all chronic insomnia diagnoses under a single disorder, chronic insomnia disorder. Chronic insomnia requires a report of a sleep initiation or sleep maintenance problem, adequate opportunity and circumstances to sleep, and daytime consequences as a result of the insomnia symptoms.

To meet diagnostic criteria for chronic insomnia disorder, the patient should have symptoms at least three times per week over a duration of at least 3 months. Since insomnia is a component of many psychiatric and medical conditions, a diagnosis of chronic insomnia disorder should be considered only when the insomnia is very prominent and it requires further evaluation and treatment.

Short-Term Insomnia Disorder

A diagnosis of short-term insomnia must meet the same criteria as chronic insomnia except that the symptoms have been present for less than 3 months. The development is often temporally related to a significant stressor. To make this diagnosis, the insomnia must be an independent focus for the patient or require separate clinical attention. This type of insomnia often resolves when the stressor does, or when the patient develops adequate coping mechanisms or adapts to the stressor (American Academy of Sleep Medicine 2014). However, in some cases this may evolve into chronic insomnia.

Transient insomnias (1-2 days) are also common and are typically caused by an environmental acute stressor, jet lag, or shift work and do not often require pharmacological treatments. However, pharmacotherapy with benzodiazepine hypnotics or other hypnotics may have less risks because dependence on the treatment is unlikely to develop when the therapy lasts less than 10 days.

It is particularly important that transient and short-term (a few days to a few months) insomnias be recognized and treated so that they do not evolve into longer-term, enduring disorders, such as psychophysiological insomnia. In this subtype, the patient begins to worry excessively about his or her sleep, so that what may have begun as a brief period of insomnia during a stressful time transitions into a behaviorally learned chronic sleep disorder that does not resolve once the stressful period is over. In psychophysiological insomnia, daily use of benzodiazepine hypnotics is also dangerous because it may lead to tolerance and dependence. The clinician should provide reassurance regarding the favorable resolution of the stressful event, and the patient should be instructed to use hypnotic medications intermittently to avoid developing tolerance. Education in proper sleep hygiene is also important to reduce the possibility of insomnia evolving into a chronic problem.

Insomnia Classifications Based on Clinical Features

Insomnia also can be classified on the basis of individual clinical features: sleep initiation, sleep maintenance, and termination (early morning awakening). These clinical features are still important because they can be objectively evaluated with polysomnography. Some clinical features are known to be associated with certain clinical conditions, such as nocturnal awaking and early morning wakening in elderly insomnia and early morning wakening in depression. These clinical features also determine the pharmacological target and relevant properties in selecting treatments. For example, the most important pharmacological properties to consider when selecting a hypnotic for treatment are how quickly it acts and how long the effects last (see Table 44-2 for commonly used compounds). The rate of absorption is the most critical factor determining onset of action, and T_{max} is the pharmacological parameter that best predicts onset of action. After absorption, hypnotics are distributed to various organs; distribution and drug elimination influence the duration of action. The elimination half-life (see Table 44-2) usually provides a good first estimate of the duration of action for drugs that have comparable absorption and distribution profiles. Hypnotics with a long duration of action are helpful for patients who have difficulty both initiating and maintaining sleep. One advantage of these long-acting compounds is that rebound insomnia is often delayed and milder if the drugs have to be withdrawn (see Figure 44-7). Patients who have difficulty initiating sleep might prefer short-acting compounds; however, for these compounds, it may be necessary, paradoxically, to switch to longer-acting hypnotics before withdrawing all hypnotic treatment.

A recent study conducted a network meta-analysis of comparisons of the efficacy and safety of hypnotics for insomnia, including total sleep time, sleep latency, and wake after sleep onset, in 24 articles with 5,917 older adults (Chiu *et al.* 2021). Eszopiclone and low-dose doxepin were ranked as the optimal therapy for prolonging objective and subjective total sleep time (+ 26.69 and + 28.19 minutes), respectively, compared with placebo. Zaleplon was the most effective therapy in reducing objective and subjective sleep onset latency ([?] 21.63 and [?] 15.86 minutes) compared with control. Temazepam was the best treatment for objective and subjective wake after sleep onset ([?] 25.29 and [?] 22.25 minutes) compared with control. Low-dose doxepin appeared to be the most effective treatment for increasing objective sleep efficiency (6.08% improvement vs. placebo). Triazolam showed a higher overall risk of adverse events (OR, 1.96, 95% CI: 1.03-3.74) when compared with zaleplon.

The importance of determining whether insomnia is the symptom of an underlying neuropsychiatric condition must be emphasized (see Chapter 58 in this textbook, "Treatment of Insomnia"). If depression is a contributing factor, a sedating antidepressant such as amitriptyline, doxepin, or trazodone can be used either alone or in combination with a hypnotic agent (see Chapter 48, "Treatment of Depression"). Patients with schizophrenia can experience persistent insomnia (affecting both initiation and maintenance of sleep), and antipsychotics with sleep-enhancing effects, such as olanzapine or quetiapine, may be effective therapies (see Chapter 53, "Treatment of Schizophrenia"). For insomnia associated with anxiety disorders, hypnotics supplemented with anxiolytics can be used (see Chapter 50, "Treatment of Anxiety Disorders").

Special Considerations for Insomnia Treatment in Older Adults

Sleep disturbances are very common complaints in old age, and treatment must be initiated carefully in this population. Between 5% and 33% of older adults in North America and the United Kingdom are prescribed a benzodiazepine or a benzodiazepine receptor agonist (e.g., zolpidem, zopiclone, zaleplon) for sleep problems (Aparasu *et al.* 2003; Craig *et al.* 2003; Gottlieb 1990; Jaussent *et al.* 2013), and this segment of the population receives 35%-40% of all sedative-hypnotic prescriptions (Gottlieb 1990).

Before pharmacological therapy is started, all possible causes of insomnia should be examined (e.g., psychophysiological; associated with drugs or alcohol; due to disturbance of the sleep-wake cycle; associated with periodic leg movements, sleep apnea, or other physical or psychiatric conditions). Likewise, before selecting a specific hypnotic, the clinician should consider its pharmacological properties and side effect profile, the patient's medical health and medical history, and the patient's history of sedative-hypnotic use. The special case of melatonin and melatonin receptor agonists was discussed earlier in this chapter (see section "Other Sedative-Hypnotic Compounds"). It is expected that data on the efficacy of orexin receptor antagonists for older adults will be accumulated in the near future.

Hypnotics or their active metabolites often accumulate during chronic use in older adults, and this accumulation may cause cognition problems, disorientation, confusion, and (occasionally) falls. Hypnotics with short or intermediate half-lives are thus recommended, and the lowest dosage possible should be used. Compounds with a short half-life, such as triazolam or zolpidem, may be effective for problems with sleep initiation and sleep fragmentation. Zolpidem has little muscle relaxant effect and may be preferable to triazolam. Compounds with an intermediate hypnotic profile, such as estazolam or temazepam, are also reported to be effective for older adults. Hypnotics with intermediate half-lives may alter daytime performance and memory to a lesser extent and are not as likely to induce rebound insomnia after withdrawal as are regular hypnotics.

Mode of action is another important factor to consider in the selection of compounds to treat insomnia. The older sedative-hypnotics compounds probably act on the executive system for sleep induction (i.e., enhancing GABA-mediated sleep induction). It is still unknown whether benzodiazepine endogenous ligands exist and whether such abnormalities are involved in certain types of insomnias. These classes of compounds may be effective in various insomnias regardless of their causes but do not affect the disease conditions. In contrast, two new classes of hypnotics, orexin receptor antagonists and melatonin receptor agonists, specifically block and enhance endogenous orexinergic and melatonergic neurotransmissions, respectively. In animal experiments, it was reported that orexin receptor antagonists do not increase sleep induction when animals have normal sleep amounts, unlike the classic sedative-hypnotics (Gotter *et al.* 2016). It is also known that orexin receptor antagonists do not induce sleep in orexin-neuron-deficient mouse models (Beuckmann *et al.* 2019; Gotter *et al.* 2016; Mang *et al.* 2012). Therefore, these new classes of compounds may more specifically act on insomnias with abnormalities via orexinergic and melatonergic neurotransmission.

Conclusion

The mechanism of action of most currently available hypnotics (benzodiazepines, barbiturates, alcohol, and recent nonbenzodiazepine hypnotics) involves a modulatory effect of GABAergic activity. These compounds stimulate GABAergic transmission by acting on the $GABA_A$-benzodiazepine-Cl^- macromolecular complex, known to contain multiple modulatory binding sites and many receptor subtypes. This recently discovered molecular diversity within the macromolecular complex suggests that new GABAergic hypnotic compounds, including recently developed nonbenzodiazepine hypnotics with subtype selectivity, may have better side effect profiles.

Other non-GABAergic hypnotics, including mostly sedative antidepressants, antihistamines, melatonin and melatonin receptor agonists, and most recently orexin receptor antagonists, are viable strategies in the treatment of insomnia, especially because these hypnotics may lack some of the hampering side effects often seen with classic GABAergic hypnotics, such as abuse potential and amnesic effects. Their prescription, like that of regular benzodiazepine-like hypnotic compounds, should be guided by the knowledge that insomnia is a heterogeneous condition that should be explored clinically before any pharmacological treatment is initiated.

CHAPTER 45

Psychostimulants and Wakefulness-Promoting Agents

Charles DeBattista, D.M.H., M.D.

Amphetamine, first discovered in 1887, and the subsequently developed stimulants have been used in clinical psychiatry with varying results. Beyond their use for ADHD, stimulants have been used for symptomatic relief based on their effects on mood and hedonic drive. Research into the use of stimulants as adjunctive agents in the treatment of specific symptoms and syndromes has been increasing. Various common adjunctive psychotherapeutic uses for stimulants, such as depression, have not been well researched, whereas other indications, such as narcolepsy, are backed by considerable clinical data. In this chapter, I review the pharmacology of these medications and their indications (Tables 45-1 and 45-2).

TABLE 45-1. FDA classifications of psychostimulants and wakefulness-promoting agents

Agent	Schedule	Approved for	Medication type	Abuse potential

Note. OSAHS = obstructive sleep apnea/hypopnea syndrome; SWSD = shift-work sleep disorder.
Source. Data from *Physicians' Desk Reference*, 60th Edition. Montvale, NJ, Medical Economics Company, 2006.

Agent	Schedule	Approved for	Medication type	Abuse potential
Amphetamine	II	ADHD, narcolepsy	Anorexiant/stimulant	Black box warning
Lisdexamfetamine	II	ADHD, binge eating	Stimulant	Black box warning
Methylphenidate	II	ADHD, narcolepsy	Anorexiant/stimulant ("mild stimulant")	Black box warning
Modafinil	IV	Excessive daytime sleepiness associated with narcolepsy, OSAHS, and SWSD	Wakefulness-promoting agent	Reinforcing
Armodafinil	IV	Excessive daytime sleepiness associated with narcolepsy,	Wakefulness-promoting agent	Reinforcing

Note. OSAHS = obstructive sleep apnea/hypopnea syndrome; SWSD = shift-work sleep disorder.
Source. Data from *Physicians' Desk Reference*, 60th Edition. Montvale, NJ, Medical Economics Company, 2006.

Agent	Schedule	Approved for	Medication type	Abuse potential
		OSAHS, and SWSD		

Note. OSAHS = obstructive sleep apnea/hypopnea syndrome; SWSD = shift-work sleep disorder.
Source. Data from *Physicians' Desk Reference*, 60th Edition. Montvale, NJ, Medical Economics Company, 2006.

TABLE 45-2. Amphetamine and methylphenidate preparations

Stimulant	Time to effect	Peak (hours)	Duration (hours)	Dosing
Amphetamine preparations				
Adderall[a]	~ 1 hour	3	6 -9	bid
Adderall XR	1-2 hours	7	6 -10	qd (or bid)
Dexedrine	1 hour	3	4 -6	bid or tid
Dexedrine Spansules	1 hour	4	6 -10	qd or bid
Desoxyn (methamphetamine)	40 minutes	1 -3	4 -24	qd, bid, or tid
Vyvanse (lisdexamfetamine)	~ 1 hour	2	9	qd
Methylphenidate preparations				
Methylphenidate	15-30 minutes	1 -2	4 -5	bid or tid
Focalin (dexmethylphenidate)	15-30 minutes	1 -2	4 -5	bid or tid

[a] Amphetamine/dextroamphetamine, 1:3 ratio.

[b] Laser hole in capsule allows passage of drug; osmotically active push layer expels drug.

[c] Rapid-release and continuous-release beads give biphasic response.

Stimulant	Time to effect	Peak (hours)	Duration (hours)	Dosing
Ritalin SR (tablet)	1-2 hours	5	8	qd or bid
Concerta[b]	1-2 hours	6 -8	12	qd or bid
Metadate-CD[c]	1 hour	Biphasic: 1-2 and 4-5	6 -8	qd or bid
Jornay-PM	8-9 hours	14 -16 hours	6 -8	qhs
Azstarys	1-2 hours	2.0 -4.5	6 -8	qd

[a] Amphetamine/dextroamphetamine, 1:3 ratio.

[b] Laser hole in capsule allows passage of drug; osmotically active push layer expels drug.

[c] Rapid-release and continuous-release beads give biphasic response.

Amphetamines

Structure-Activity Relations

Structurally, amphetamine is phenylisopropylamine. Ultimate pharmacological action is determined by alterations to any of the three basic parts of the amphetamine molecule.

Amine Changes

In terms of affecting clinical utility, substitution at the amine group is the most common alteration. Methamphetamine (both L and D isomers), which is characterized by an additional methyl group attached to the amine, making it a secondary substituted amine, is more potent than amphetamine. Usefully, one may think of the amine group as enhancing stimulant-like properties.

Isopropyl Changes

An intact isopropyl side chain appears to be needed in order to maintain the potency of amphetamine. For example, changing the propyl to an ethyl chain creates phenylethylamine, an endogenous neuroamine (a metabolite of the monoamine oxidase inhibitor [MAOI] phenelzine) that has mood-and energy-enhancing properties but less potency and a much shorter half-life than amphetamine (Janssen *et al.* 1999).

Aromatic Changes

Substitutions on the phenyl group are associated with a decrease in amphetamine-like properties. Interestingly, reduction of the phenyl to a cyclohexyl ring reduces the potency, but not the efficacy, of amphetamine properties. Unlike changes at the amine or isopropyl level, additions to the aromatic ring substantially alter the effects of the compound. The most common changes at the aromatic ring are of the methoxy type and are associated with hallucinogenic properties.

Stereospecificity

In recent years there has been renewed interest in drugs that are pure stereoisomers, as opposed to racemic mixtures, especially with the release of dexmethylphenidate (the dextro isomer of methylphenidate) and escitalopram (the levo isomer of citalopram).

In amphetamine isomers, it is true that the dextro form (i.e., dextro isomer, or dextroamphetamine) is almost twice as potent as the levo form (i.e., levo isomer, or levoamphetamine) in promoting wakefulness, but they are of equal potency in reducing cataplexy and rapid eye movement (REM) sleep (Nishino and Mignot 1997). The effect on dopamine reuptake is stereospecific; inhibition in rat brain, striatum, and hypothalamus has been found to be markedly different between the two isomers (Ferris and Tang 1979).

The clinical utility of stereospecificity is unclear. Urine levels of the levo isomer have been used to measure compliance in amphetamine-addicted patients prescribed dextroamphetamine for maintenance or detoxification; the logic is that the more levo isomer present in urine, the less compliance (George and Braithwaite 2000).

Perhaps the most clinically useful difference between amphetamine isomers involves their differential effects on reinforcement. Studies in rats have shown that the dextro isomer is four times more potent than the levo isomer in promoting lever pressing for intracranial stimulation (Hunt and Atrens 1992). However, that pure dextroamphetamine is better for the treatment of ADHD than, for example, the mixed salts of dextroamphetamine/amphetamine is neither obvious nor conclusively shown. In addition, the overall greater potency of the dextro form for central actions suggests that this form may have a higher potential for abuse.

Pharmacological Profile

Amphetamines are noncatecholamine, sympathomimetic amines with CNS stimulant activity that causes catecholamine efflux and inhibits the reuptake of these neurotransmitters (see subsection "Mechanism of Action" later in this section).

Pharmacokinetics and Disposition

Amphetamine is highly lipid soluble and reaches peak levels in approximately 2 hours. Because of this lipid solubility, amphetamine has rapid distribution into tissues and transit across the blood-brain barrier. The protein binding is highly variable, but the average volume of distribution (V_d) is 5 L/kg.

The half-life of amphetamine is approximately 16-30 hours. On average, 30% of amphetamine is excreted unchanged.

Multiple extended-release preparations of both methylphenidate and amphetamine have been created to allow the drug to be taken only once a day. In addition, a delayed-onset preparation of methylphenidate allows the patient to take the drug in the evening but not have the onset of effect until the next day.

For patients, the Medication Guides issued with many prescribed drugs provide information about the available dosage forms, strengths, and markings (U.S. Food and Drug Administration 2023). These handouts are valuable for educating patients about proper use of drugs and potential side effects and can help reduce the risk of medication errors and severe adverse effects.

Mechanism of Action

The classic mechanism of action of amphetamine involves rapid diffusion directly into neuron terminals; through dopamine and norepinephrine transporters, amphetamine enters vesicles, causing release of dopamine and norepinephrine (Hutson *et al.* 2014). The release of these neurotransmitters into the synapse mediates some of the psychological and motoric effects of amphetamine, including euphoria, increased energy, and locomotor activation.

Side Effects and Toxicology

The side effects of amphetamines are predictable relative to their sympathomimetic pharmacology. The most common effects are nervousness, agitation, and decreased sleep. Serious adverse consequences have been observed with amphetamines and include arrhythmias, hyperpyrexia, rhabdomyolysis, and convulsions. Death, although uncommon, generally occurs only after the manifestation of one of these symptoms. Hallucinosis and psychosis are common complications of injected or inhaled amphetamines but are uncommon with oral intoxication.

Methamphetamine is more frequently associated with complications; because of its higher toxicity, it is not clear whether severe complications are dose dependent. For example, in a retrospective study of methamphetamine-related deaths in a large city, methamphetamine use was significantly associated with a higher risk of coronary artery disease, as well as a higher rate of subarachnoid hemorrhage, although it was of course impossible to determine whether the subjects were first-time users or chronic users (Karch *et al.* 1999). Of particular note in this study, blood levels of methamphetamine did not differ between the group in which methamphetamine was judged to be the cause of death and the group in which methamphetamine was detected but judged not to be related to the cause of death, suggesting that these toxicities are not necessarily dose dependent. Similarly, in one 5-year study, methamphetamine accounted for 43% of rhabdomyolysis cases in an emergency department setting.

Methamphetamine is more neurotoxic than amphetamine; it can cause destruction of dopaminergic neurons in the basal ganglia and thus is widely thought to increase the likelihood of future parkinsonism (Callaghan *et al.* 2012; Granado *et al.* 2013; Guilarte 2001). Although it is commonly believed that MDMA (3,4-methylenedioxy-*N*-methamphetamine, "ecstasy") is toxic primarily to serotonergic neurons (Sprague *et al.* 1998), evidence shows that it is also toxic to dopaminergic neurons (Simmler and Liechti 2018).

Seizures are fairly common in amphetamine misuse scenarios, especially with the more potent methamphetamine and hallucinogenic analogs.

Stimulant psychosis--often referred to as paranoid psychosis--is also common in amphetamine misuse scenarios because of the overwhelming presentation of the eponymous symptom (Chiang *et al.* 2019). Visual hallucinations are also disproportionately common with amphetamine psychosis. Psychosis is often seen together with stereotypy. In humans, stereotypy can take many forms but usually is expressed as pacing, searching, or examining minute details.

Drug-Drug Interactions

A comprehensive review found that drug interactions with amphetamine were mostly pharmacodynamic (Markowitz and Patrick 2001); however, because a small portion of amphetamine metabolism occurs via the cytochrome P450 (CYP) 2D6 isoenzyme, drugs that inhibit 2D6 metabolism can, theoretically, have the effect of increasing the plasma level of amphetamine.

Lisdexamfetamine

Lisdexamfetamine dimesylate, a prodrug that on absorption is metabolized to dextroamphetamine and L-lysine, was approved in 2007 for the treatment of ADHD and in 2014 was approved for the treatment of binge-eating disorder in adults. Food does not affect absorption of lisdexamfetamine, but acidification of the urine results in more rapid clearance.

Two small studies of children found good efficacy and tolerability for lisdexamfetamine in the treatment of ADHD. A 4-week randomized, double-blind, forced-dose, parallel-group study compared lisdexamfetamine 30, 50, or 70 mg/day with placebo in children (ages 6-12 years) with ADHD (Biederman *et al.* 2007b). Efficacy, as measured by scores on the ADHD Rating Scale-Version IV, the Conners Parent Rating Scale, and the Clinical Global Impression-Improvement (CGI-I) scale, was statistically superior to that of placebo for all dosages tested. A randomized, double-blind, placebo-controlled crossover study compared lisdexamfetamine with placebo and extended-release mixed amphetamine salts (Adderall XR) in 52 children (ages 6-12 years) with ADHD in an analog classroom setting (Biederman *et al.* 2007a). The study found comparable efficacy and safety for the active medications and superiority over placebo as measured by scores on the CGI-I scale and the Swanson, Kotkin, Agler, M-Flynn, and Pelham Deportment subscale. In a 4-week forced-dose (30, 50, or 70 mg/day) study of 420 adults with ADHD, lisdexamfetamine was found to have significantly greater efficacy over placebo as measured by ADHD Rating Scale scores. Human liability studies have also found lower abuse-related drug-liking scores compared with immediate-release D-amphetamine at equivalent dosages (Najib 2009).

The approval of lisdexamfetamine for binge-eating disorder was based on several large registration trials. The registration trials involved more than 700 patients with moderate to severe binge-eating disorder. In a Phase II trial, subjects were randomly assigned to 30, 50, or 70 mg/day lisdexamfetamine or placebo for 3 weeks and maintained at this dosage for an additional 8 weeks. Compared with placebo, the 50-mg/day and 70-mg/day dosages were more effective in reducing the total number of binge-eating days, were more likely to result in a remission of symptoms, and produced greater global improvement (McElroy *et al.* 2015a). Subsequent to that study, two Phase III trials have evaluated the efficacy and safety of lisdexamfetamine (target dosage of 50 or 70 mg/day as tolerated) versus placebo in adults ages 18-55 years with binge-eating disorder. Lisdexamfetamine at both dosages was more effective than placebo in reducing the total number of binge days. The active treatment groups showed a reduction in binge-eating days from an average of 5 days/week to 1 day/week (versus a reduction to about 2 days/week in the placebo group). Compared with subjects who received placebo, those who received active treatment experienced greater overall improvement, as measured by the CGI-I score (McElroy *et al.* 2016).

A number of preliminary studies suggested that lisdexamfetamine might be useful as an adjunctive treatment for major depressive disorder. Trivedi *et al.* (2013) found that 20-50 mg of lisdexamfetamine added to escitalopram for 6 weeks was superior to placebo in treating residual symptoms of depression. However, two subsequent Phase III randomized controlled trials failed to demonstrate a significant benefit for lisdexamfetamine over placebo in the adjunctive treatment of major depressive disorder (Corp *et al.* 2014; Giacobbe *et al.* 2018). Still, there is some evidence that lisdexamfetamine may be more effective than placebo in treating executive function deficits in patients with major depressive disorder (Madhoo *et al.* 2014) and that it may have a role in the treatment of bipolar depression (McElroy *et al.* 2015b).

Methylphenidate

Methylphenidate has FDA-approved indications for the treatment of ADHD and narcolepsy.

Structure-Activity Relations

Although methylphenidate has two chiral centers, only one contributes to its clinical effect. The D- and L-threo enantiomers are in a racemic mixture, although a single-isomer form of methylphenidate, dexmethylphenidate [*(R,R)*-(+)], is currently being marketed under the brand name Focalin.

There are some differences in the pharmacological parameters of the two isomers, as described in the following subsection (Mariotti *et al.* 2013).

Pharmacokinetics and Disposition

Methylphenidate is almost totally absorbed on oral administration (as is the single isomer dexmethylphenidate), although it is absorbed at a faster rate in the presence of food than without food (Chan *et al.* 1983). Methylphenidate has low protein binding (15%) and is fairly short acting; the effects last approximately 4 hours, with a half-life of 3 hours. The primary means of clearance is through the urine, in which 90% is excreted.

Mechanism of Action

Although it is both a norepinephrine and a dopamine reuptake inhibitor, methylphenidate appears to exert its effects primarily through its action on dopamine neurobiology. It blocks the dopamine transporter and increases extracellular dopamine (Mariotti *et al.* 2013). The amount of extracellular dopamine increase varies greatly among individuals, depending on the extent of both dopamine transporter blockade and baseline dopamine release.

Side Effects and Toxicology

The common side effects of methylphenidate are similar to those of amphetamine and include nervousness, insomnia, and anorexia, as well as dose-related systemic effects such as increased heart rate and blood pressure. Overdose may lead to seizures, dysrhythmias, or hyperthermia (Klein-Schwartz 2002). At therapeutic dosages, discontinuation symptoms tend to be slight, but with chronic use, symptoms similar to those in amphetamine withdrawal, including lethargy, depression, and paranoia, can occur (Klein-Schwartz 2002).

Drug-Drug Interactions

Although theoretically a substrate of CYP2D6, methylphenidate was found not to have any significant metabolism in humans via this enzyme (DeVane *et al.* 2000). The prescribing information (Novartis 2021) does cite methylphenidate's potential ability to inhibit the metabolism of warfarin, some antiepileptic agents, and tricyclic antidepressants (TCAs), and therefore caution should be observed. However, a review found that methylphenidate is safe and has minimal drug-drug interactions, with the exception of concomitant MAOI use (Markowitz and Patrick 2001).

Modafinil

Modafinil was the first FDA-designated "wakefulness-promoting agent"; it is approved by the FDA for the treatment of excessive sleepiness associated with narcolepsy, sleep apnea, and residual sleepiness after standard treatment for shift-work sleep disorder (SWSD) (Cephalon Inc. 2008). As described below, modafinil does little to prevent or alter sleep when one is trying to do so; however, it appears to permit more stable wakefulness (i.e., reduced sleep propensity) when one is attempting to stay awake in the presence of elevated sleep pressure.

Structure-Activity Relations

Modafinil (2-[(diphenylmethyl)sulfinyl]acetamide) exists in racemic form. Both stereoisomers appear to have the same activity in animals.

Pharmacokinetics and Disposition

Modafinil, the primary metabolite of adrafinil, lacks many of the side effects found in adrafinil, such as increased liver enzymes, anxiety, and stomach pain. Modafinil is rapidly absorbed but slowly cleared. It has fairly high protein binding (60%) and a V_d of 0.8 L/kg. Its half-life is 11-14 hours.

The metabolism of modafinil is complex. In contrast to excretion of amphetamines, less than 10% of modafinil is excreted unchanged.

Metabolism is primarily via CYP3A4/5. It has been reported that modafinil also has in vitro capacity to induce CYP3A4 (Robertson *et al.* 2000), especially gastrointestinal 3A4. A clinically significant reduction of triazolam has been reported (Robertson *et al.* 2002).

Mechanism of Action

The precise mechanism by which modafinil exerts its wakefulness-promoting effect in patients with excessive sleepiness due to narcolepsy is not yet known. Not surprisingly, given its efficacy in narcolepsy, modafinil is not observed to increase c-Fos activity in hypocretin cells, as well as in the tuberomammillary nucleus (which is primarily histaminergic), striatum, and cingulate cortex at higher dosages (Scammell *et al.* 2000). Additionally, in rats, an increase in histamine release in the anterior hypothalamus is seen (Ishizuka *et al.* 2003). However, modafinil's wakefulness-promoting effects were not decreased in histamine knockout mice (Bonaventure *et al.* 2007).

What may be an important aspect of the pharmacology of modafinil is its lack of effect on the neuroendocrine system. A comparison of healthy volunteers who were sleep deprived for 36 hours without modafinil with those who received modafinil during sleep deprivation found no difference in cortisol, melatonin, or growth hormone levels (Brun *et al.* 1998).

Side Effects and Toxicology

Modafinil appears to be well tolerated, with the most common side effects being headache and nausea. Side effects have been found to increase with dosages from 100 to 600 mg/day, and very high dosages (800 mg/day) have been found to be associated with higher rates of tachycardia and hypertension (Wong *et al.* 1999). Overall, only 5% of the patients in Phase III trials discontinued modafinil because of side effects (Cephalon Inc. 2008).

Modafinil appears to be fairly safe at high dosages. Reports indicate that 32 patients have safely taken 1,000 mg/day for more than 50 days; one patient safely took 1,200 mg/day for 21 consecutive days. Two patients took 4,000 mg and 4,500 mg, respectively, in a single dose and experienced only transient (< 24 hours) agitation and insomnia with mild elevations in heart rate and blood pressure (Cephalon Inc. 2008). There have been no reports of seizures with modafinil.

During the attempts to obtain FDA approval of modafinil for the treatment of ADHD, concerns arose over the possibility that modafinil may carry a risk of Stevens-Johnson syndrome. Three cases of drug-induced rash were reported during clinical trials (U.S. Food and Drug Administration 2007).

The package insert notes a risk of "serious rash, including Stevens-Johnson syndrome," in adults and children and cautions that modafinil is not indicated for children. The insert cites a rash incidence of 0.8% in pediatric patients, with one case of possible Stevens-Johnson syndrome and one case of multiorgan hypersensitivity reported, and concludes with the statement that although there are no known predictive factors, benign rashes do occur, and modafinil should be discontinued if rash develops.

Drug-Drug Interactions

As described earlier in this section, modafinil induces CYP3A4/5 and thus conceivably could lower the plasma concentrations of medications with substantial 3A4/5 metabolism. However, it is not clear whether this induction is substantial only on the gastrointestinal cytochrome and is thus relevant only for other drugs undergoing significant first-pass metabolism (Darwish *et al.* 2010).

Modafinil inhibits CYP2C19 in vitro (Robertson *et al.* 2000). It is prudent to assume that the effect of modafinil on the cytochrome system is not well characterized and to be vigilant for these potential drug-drug interactions.

Armodafinil

Armodafinil (l-*[R]*-modafinil or [[?]]-*[R]*-modafinil) is the longer-acting isomer of racemic modafinil. In 2007, armodafinil received FDA approval for the same indications as modafinil, specifically excessive sleepiness associated with narcolepsy, obstructive sleep apnea/hypopnea syndrome (OSAHS) as an adjunct to standard treatment, and SWSD.

Armodafinil and racemic modafinil produce comparable peak plasma concentrations, although the peak for armodafinil occurs later than that for modafinil and is maintained for 6-14 hours postdose (Dinges *et al.* 2006).

Armodafinil has been studied in multiple randomized controlled trials in the treatment of sleep disorders. For example, two early 12-week double-blind studies using armodafinil 150 mg as an adjunct to continuous positive airway pressure (CPAP), both in patients who were otherwise stable except for some residual sleepiness (Hirshkowitz *et al.* 2007) and in patients who were still symptomatic (Roth *et al.* 2006), found improvements in wakefulness measures. Armodafinil also significantly improved the quality of episodic secondary memory (i.e., the ability to recall unrehearsed information). Whether this effect was due directly to the medication, to improved wakefulness, or to decreased hypoxia (as a function of being more awake) is unclear. However, armodafinil did not adversely affect the CPAP or any other physiological parameters.

A 12-week double-blind study of armodafinil in narcolepsy found improvements similar to those seen with modafinil. These included improved wakefulness (as measured by the Maintenance of Wakefulness Test), improved Clinical Global Impression of Change (CGI-C) scores, and improvement in memory and attention. Armodafinil 150 mg/day and 250 mg/day were similarly effective (Harsh *et al.* 2006).

In SWSD, armodafinil 150 mg/day was tested against placebo in a 12-week study, showing significant prolongation of time to sleep onset and an improvement in overall clinical condition based on CGI-C scores. Armodafinil had no effect on daytime sleep polysomnography (Roth *et al.* 2005).

Daytime sleepiness has been implicated in an increased risk of motor vehicle accidents in patients with obstructive sleep apnea. Armodafinil has demonstrated efficacy for patients with obstructive sleep apnea in improving alertness in driving simulations without affecting compliance on CPAP (Kay and Feldman 2013).

Clinical Uses of Stimulants and Wakefulness-Promoting Agents

Although stimulants have been used for many years in a number of clinical scenarios, double-blind, randomized controlled trials examining their safety, efficacy, and effectiveness in neurobehavioral disorders other than ADHD are rare. Most of the support for their use comes from open-label studies and case series. Randomized trials of modafinil for neurobehavioral disorders with symptoms of sleepiness and fatigue are beginning to be published.

Attention-Deficit/Hyperactivity Disorder

Multiple double-blind, placebo-controlled studies have shown the efficacy of stimulants for ADHD, and their use is well investigated in both adults and children (Greenhill *et al.* 2002; Wilens *et al.* 2002). Some studies are aimed at showing the superiority of one preparation relative to another, although this approach is not always fruitful; for example, one study comparing various single-dose amphetamine preparations with one another and with placebo over 8 weeks found that they were all superior to placebo (James *et al.* 2001). However, immediate-release amphetamines had a faster onset but shorter duration of action; spansules, although much slower to take effect than the others, lasted several hours longer.

With respect to individual stimulants, all appear to be equally efficacious in the treatment of ADHD, but they have been reported to have different time courses. In a double-blind, double-control (placebo and methylphenidate) study, the mixed amphetamine salts of Adderall were found to exert their effects rapidly but to dissipate quickly over the course of the day, although Adderall lasted longer than methylphenidate (Swanson *et al.* 1998). Notably, higher doses of Adderall lasted longer than lower doses, indicating a dose-dependent effect in duration of action not found with methylphenidate. Thus, although stimulants may appear to be of equal efficacy overall, there is considerable variability in individual response to each stimulant.

The decision to choose amphetamines or methylphenidate for the treatment of ADHD is often based on the clinician's preference and degree of experience with the medication. At least one important blinded crossover study found that in performance tasks, the two drugs were generally equally efficacious (Efron *et al.* 1997).

Modafinil is not FDA approved for the treatment of ADHD but has shown some efficacy in clinical trials. A 4-week double-blind study with an 8-week open-label extension found modafinil to be efficacious across all ADHD rating subscales for the duration of the open-label extension (Boellner *et al.* 2006). Interestingly, 10% of the 220 children studied lost an average of 3 kg, while 4% gained the same amount. Another such double-blind study found significant efficacy with a dosage of 300 mg/day, although heavier children ([?] 30 kg) needed 400 mg/day (Biederman *et al.* 2006). A pooled analysis of three trials (638 patients) found that modafinil produced similarly greater and impressive improvements in ADHD rating scale scores for both stimulant-naive and prior-stimulant subgroups relative to placebo (Wigal *et al.* 2006). As in other studies, insomnia and headache were the most common side effects but were infrequent overall. A 9-week trial (Biederman *et al.* 2005) found that almost half of patients (mean age 10 years, mean dosage 368 mg/day) were much or very much improved, and efficacy was seen in both inattentive and hyperactive subgroups and both school and home ratings. Some small but controlled trials (Rugino and Samsock 2003; Turner *et al.* 2004) found efficacy with modafinil, and in one study (Taylor and Russo 2000), equivalence to dextroamphetamine was shown. Modafinil is currently indicated only for the treatment of excessive sleepiness associated with narcolepsy, OSAHS, and SWSD.

Stroke and Traumatic Brain Injury

The results of studies on the effects of stimulants on patients who had strokes or traumatic brain injury are mixed. Although small early studies showed some superiority of amphetamine to placebo in improving motor function poststroke (Crisostomo *et al.* 1988; Walker-Batson *et al.* 1995), subsequent, more carefully controlled studies of amphetamine in geriatric stroke patients did not show superiority to placebo in improving motor function (Goldstein *et al.* 2018; Sonde *et al.* 2001). Neither was amphetamine found to be superior to placebo in improving somatosensory training outcomes (Knecht *et al.* 2001). Modafinil also has not been consistently effective in the treatment of fatigue associated with traumatic brain injury (Jha *et al.* 2008). In contrast, relative to placebo, dextroamphetamine 10 mg/day significantly improved language recovery in poststroke aphasic patients when immediately coupled with a session of speech therapy; this effect was seen as quickly as within 1 week (Walker-Batson *et al.* 2001). A review lamented the lack of good data in brain-injured patients but did note that available data suggest that the bulk of stimulant efficacy may lie with its improvements in mood and cognitive processing (Whyte *et al.* 2002).

Although there is a dearth of placebo-controlled studies, there are some interesting reports in which stimulants were compared with antidepressants for patients with poststroke depression. One such study, comparing methylphenidate with TCAs, found similar and significant response to both drugs, although the stimulant worked faster (Lazarus *et al.* 1994).

Modafinil has been reported to have therapeutic efficacy in some types of brain injury. Two double-blind studies by the same group (Saletu *et al.* 1990, 1993) found modafinil effective in improving cognition and accelerating improvement in attention and concentration for patients with alcoholic brain syndrome. Similarly, Joos *et al.* (2013) found that 10 weeks of modafinil treatment significantly improved working and verbal memory for patients with DSM-IV-defined alcohol dependence. In addition, there is some evidence that modafinil may help with cognition for patients with traumatic brain injury (Dougall *et al.* 2015; Maksimowski and Tampi 2016).

Cocaine and Stimulant Use Disorders

It may not be surprising that a double-blind study showed sustained-release dextroamphetamine to be superior to placebo in reducing cocaine use (Grabowski *et al.* 2001). However, similarly designed studies by the same authors did not find this effect with methylphenidate (Grabowski *et al.* 1997) or with risperidone (Grabowski *et al.* 2000). A double-blind, placebo-controlled study found that modafinil did not increase the euphoria or craving for cocaine; in fact, it may have blunted the euphoria (Dackis *et al.* 2003). A double-blind, placebo-controlled study of 62 patients found that modafinil-treated patients had a longer duration of cocaine abstinence (> 3 weeks), with no dropouts due to adverse events (Dackis *et al.* 2005). Likewise, a 48-day double-blind trial found that under controlled laboratory conditions, modafinil significantly attenuated self-administration and effects of cocaine (Hart *et al.* 2008). However, a large randomized controlled study of modafinil in the treatment of 210 subjects with DSM-IV-TR (American Psychiatric Association 2000)-defined cocaine dependence did not find modafinil generally efficacious in improving abstinence from cocaine use (Dackis *et al.* 2012), although there was a trend for male patients receiving a modafinil dosage of 400 mg/day to be less likely to use cocaine. More study is needed to determine which, if any, patients with cocaine dependence might benefit from modafinil treatment.

Alcohol Use Disorder

Basic research suggests that amphetamine appears to have an unexpected effect in alcohol use disorder. In rats, amphetamines reduced alcohol consumption during choice trials; this reduction was specific to alcohol intake, because amphetamine administration had no effect on rodents' intake of water (Yu *et al.* 1997). This effect of amphetamine on alcohol consumption may involve the neurobiology of reward systems (Ellison and Potthoff 1987). Much more research is needed to identify the mechanisms by which stimulants affect alcohol intake.

Narcolepsy

Stimulants have traditionally been used to treat excessive sleepiness associated with narcolepsy. Narcolepsy is characterized by excessive sleepiness that is typically associated with cataplexy and other REM sleep phenomena such as sleep paralysis and hypnagogic hallucinations. Modafinil's approval for treatment of excessive sleepiness in narcolepsy was based on substantial evidence from large multicenter clinical trials (Broughton *et al.* 1997; U.S. Modafinil in Narcolepsy Multicenter Study Group 1998, 2000). Modafinil is less disruptive of sleep than amphetamines and is thought to have a lower abuse potential (Shelton *et al.* 1995) (see Table 45-1). One study found that taking an extra dose (200 mg) at midday improved wakefulness in patients with narcolepsy without causing insomnia at night (Schwartz *et al.* 2004). Importantly, cataplexy--the sudden occurrence of muscle weakness in association with experiencing laughter, anger, or surprise--is responsive to amphetamines but not to modafinil ("Modafinil" 1999; Shelton *et al.* 1995).

Fatigue

The use of stimulants to treat fatigue syndromes may seem intuitive, but evidence from large-scale controlled clinical trials to support this use is mixed. In one of the

only double-blind, placebo-controlled studies, men with HIV, depression, and fatigue had significantly less fatigue with dextroamphetamine (73% response [Wagner and Rabkin 2000]). Tolerance, dependence, and misuse were not observed, even across a 6-month open phase. A double-blind study of methylphenidate and pemoline in a similar group of 144 patients with HIV who had severe fatigue found both stimulants effective in improving fatigue and quality of life (Breitbart *et al.* 2001). Rabkin *et al.* (2011) found that a significant majority of HIV patients--including those with comorbid hepatitis C--reported an improvement in fatigue with armodafinil.

As with HIV, cancer-related fatigue (CRF) is strongly correlated with a negative quality of life (Curt *et al.* 2000). Stimulants have long been prescribed for CRF. In one of the larger trials of stimulants (or stimulant-like agents) in the treatment 631 patients with CRF, Jean-Pierre *et al.* (2010) found that modafinil was more effective than placebo in helping patients with severe fatigue. However, modafinil did not separate from placebo in patients with cancer and mild or moderate fatigue at baseline. Similarly, in a Phase III study of armodafinil 150 mg/day for 8 weeks in the treatment of CRF in patients with multiple myeloma, armodafinil failed to separate from placebo (Berenson *et al.* 2015). In addition, no advantage was found for armodafinil in a controlled study of the treatment of brain radiation-related fatigue (Page *et al.* 2015). On the other hand, 10 mg of methylphenidate was significantly more effective than placebo in treating CRF in 38 patients with advanced cancer who were undergoing palliative care in Denmark (Pedersen *et al.* 2020).

Two controlled trials (Adler *et al.* 2003; Hogl *et al.* 2002) found modafinil effective in reducing excessive sleepiness in patients with Parkinson's disease. Findings from open-label studies of modafinil for fatigue in multiple sclerosis (Rammohan *et al.* 2002) and myotonic dystrophy (Damian *et al.* 2001) suggest modafinil's utility in management of fatigue. However, a carefully controlled study of methylphenidate, modafinil, and amantadine in the treatment of fatigue in patients with multiple sclerosis found that none of these agents separated from placebo (Nourbakhsh *et al.* 2021). A small double-blind crossover study of modafinil in myotonic dystrophy found a reduction in fatigue but no improvement on activity measures (Wintzen *et al.* 2007). This result would be consistent with modafinil's selective effect on wakefulness and minimal impact on motor or autonomic parameters. In the same vein, studies of modafinil for patients with fibromyalgia (Schwartz *et al.* 2007) and of armodafinil for patients with sarcoidosis (Lower *et al.* 2013) did find that the medications were useful in treating the fatigue associated with these disorders.

Obstructive Sleep Apnea/Hypopnea Syndrome

There are multiple placebo-controlled studies of modafinil in the treatment of residual sleepiness in patients with DSM-IV-TR-defined obstructive sleep apnea (Chapman *et al.* 2016; Greenblatt and Adams 2021; Kingshott *et al.* 2001; Pack *et al.* 2001). These studies show modafinil's efficacy in treating the residual daytime sleepiness experienced by some patients with OSAHS who were compliant in their use of CPAP treatment.

Importantly, modafinil's use was studied in--and should be limited to--the treatment of excessive sleepiness associated with OSAHS only after CPAP has been instituted and optimized. OSAHS carries significant cardiovascular risks if the airway collapse during sleep is not treated appropriately with CPAP and related therapies. It is conceivable that lessened daytime sleepiness from use of modafinil might fool the patient into thinking that CPAP is unnecessary, thus posing a risk via the untreated underlying OSAHS.

Obesity and Binge-Eating Disorder

That amphetamines are anorectic is well known; however, the extent of the effect may be overstated. Bray and Greenway (1999) summarized the studies of obesity treatments, wherein they cited a large review of more than 200 short-term (3-month) double-blind studies of various noradrenergic agents, including amphetamine and amphetamine derivatives. Individuals taking stimulants were twice as likely as those taking placebo to lose 1 lb/week; however, the percentage of those who lost 3 lb/week was quite low (10%). A small study found that high dosages of amphetamine (30 mg/70 kg daily) decreased overall caloric intake but did so primarily through a decrease in fat consumption; carbohydrate consumption actually increased (Foltin *et al.* 1995). This mild effect on appetite is important when considering the use of stimulants by older adults who lack both energy and motivation and have a poor appetite.

The efficacy of stimulants in treating binge-eating disorder has been demonstrated in multiple studies of lisdexamfetamine. As reported earlier, Phase III randomized controlled trials demonstrate significant efficacy for lisdexamfetamine in decreasing binge-eating episodes and OCD features associated with binge eating (McElroy *et al.* 2016). Furthermore, lisdexamfetamine treatment of binge eating over a 6-month period appears to significantly reduce the risk of relapse (Hudson *et al.* 2017), and the beneficial effects of the drug on binge eating are often seen as early as the first week of treatment (McElroy *et al.* 2017).

Depression

As described earlier in this chapter, the only large-scale randomized controlled studies of a stimulant in the treatment of depression have involved lisdexamfetamine. Whereas early controlled studies suggested a benefit from adjunctive lisdexamfetamine (Trivedi *et al.* 2013) in the treatment of depression, subsequent Phase III trials failed to demonstrate the efficacy of lisdexamfetamine in the treatment of residual depressive symptoms after selective serotonin reuptake inhibitor (SSRI) treatment (Richards *et al.* 2016).

Beyond the lisdexamfetamine data, the bulk of the evidence for the utility of stimulants in the treatment of depression derives from case series by Feighner *et al.* (1985) and Fawcett *et al.* (1991), which suggested the efficacy of stimulants combined with MAOIs and MAOI/TCA combinations as well as their safety in not causing hypertensive or hyperthermic crises, and case series by Stoll *et al.* (1996) and Metz and Shader (1991), in which a combination of a stimulant and an SSRI was used. Another case series argued for amphetamine's ability to augment an antidepressant effect for patients with only partial response to their current medication; not unexpectedly, the effects were primarily in improving fatigue and apathy (Masand *et al.* 1998).

In an open-label trial of depressed patients with cancer, both amphetamine and methylphenidate were reported to improve depressive symptoms to the same extent, and effects were seen within 2 days. In this series, stimulants did not cause anorexia; in fact, they improved appetite in more than half of the patients studied (Olin and Masand 1996), suggesting that these agents are not contraindicated solely on the basis of concerns about anorexia. However, a more carefully controlled, double-blind study of 77 patients with advanced-stage cancer found no benefit of methylphenidate over placebo in treating depressive symptoms (Centeno *et al.* 2022).

In a review, Orr and Taylor (2007) noted the paucity of high-quality data and suggested a possible role for stimulants in depression, particularly as adjunctive agents, in specific patient subgroups.

The utility of modafinil in depressive states has been examined in a number of open-label and controlled studies. For example, the mood-altering properties of modafinil were studied in 32 healthy volunteers in a double-blind crossover inpatient study (Taneja *et al.* 2007). Modafinil had positive results on general mood, especially on alertness and energy measures, but also had a negative effect on calmness (i.e., increased anxiety).

A double-blind, placebo-controlled trial (Dunlop *et al.* 2007) examining the effects of modafinil initiated at the outset of treatment with an SSRI in depressed patients with fatigue found no difference in the primary outcome measure of the Epworth Sleepiness Scale but found some improvement on the hypersomnia items of the 31-item Hamilton Rating Scale for Depression. Two other controlled trials (DeBattista *et al.* 2003; Fava *et al.* 2005) and two open-label trials (DeBattista *et al.* 2001; Menza *et al.* 2000) suggest that modafinil may have some utility as an augmentation agent to antidepressants for depressed patients with fatigue or excessive sleepiness.

Both modafinil and armodafinil have shown some preliminary benefit in the treatment of bipolar depression. Frye *et al.* (2007) found that the addition of modafinil at dosages of 100-200 mg/day to a standard mood stabilizer for 6 weeks was more effective than the addition of placebo for 85 patients with bipolar depression. In a larger randomized controlled multicenter study (Calabrese *et al.* 2010), 257 patients with bipolar depression taking either lithium or valproate were randomly assigned to receive augmentation treatment with 150 mg/day armodafinil or placebo. Armodafinil appeared to help some--but not all--patients with bipolar depression, and the differences between groups did not reach statistical significance. Likewise, a study of 399 bipolar depressed patients randomly assigned to receive adjunctive armodafinil or placebo for 8 weeks failed to demonstrate armodafinil's benefit on the primary outcome measure (mean change from baseline on the 30-Item Inventory of Depressive Symptomatology-Clinician-Rated [IDS-C30] total score [Frye *et al.* 2015]). However, armodafinil was efficacious on a number of secondary measures, including IDS-C30 remission and Global Assessment of Functioning scores.

Negative Symptoms and Cognitive Deficits in Schizophrenia

Whereas positive symptoms of schizophrenia are often responsive to antipsychotics, negative symptoms and cognitive deficits are often not (Tandon 2011). Because the negative symptoms and cognitive impairments of schizophrenia are often more disabling than the positive symptoms, there has been interest in developing effective treatments for these symptoms and deficits. A number of studies have explored the efficacy of modafinil and armodafinil in the treatment of negative symptoms and cognitive deficits in schizophrenia, with mixed results. For example, whereas some studies

have found that modafinil and armodafinil improve negative symptoms (Arbabi *et al.* 2012; Kane *et al.* 2010) and working memory (Scoriels *et al.* 2012) for some schizophrenic patients, other studies have found no benefit (Bobo *et al.* 2011; Pierre *et al.* 2007; Sevy *et al.* 2005). A meta-analysis of all studies to date concluded that the benefits of modafinil and armodafinil are modest at best (Andrade *et al.* 2015). Despite these mixed results, modafinil has been well tolerated in most studies of schizophrenia. By contrast, stimulants such as dextroamphetamine may worsen positive symptoms of schizophrenia and have been less commonly studied in the treatment of negative symptoms and cognitive impairments. Further study is needed to determine the role of stimulants and wakefulness-promoting agents in schizophrenia.

Conclusion

The safety and efficacy of stimulants for the treatment of ADHD have been well established. Modafinil and armodafinil are also firmly established as efficacious wakefulness-promoting agents in narcolepsy, sleep apnea, and SWSD. The utility of these drugs in other areas is being examined. Although there is intense interest in the potential use of stimulants and modafinil in other psychiatric and neurobehavioral conditions, controlled studies of their safety and efficacy are limited, and results have been mixed. It is unclear why stimulants have not been extensively investigated for clinical utility for indications other than the treatment of ADHD. The approval of armodafinil, as the newest of the wakefulness-promoting compounds, may spur further research. Well-designed large-scale controlled trials are needed to define and characterize the role of stimulants and modafinil in various psychiatric illnesses. It is hoped that this will be an area of continued interest and development, from the elucidation of the molecular mechanisms of stimulants and modafinil/armodafinil to the demonstration, through controlled trials, of their potential clinical safety and benefits.

CHAPTER 46

Electroconvulsive Therapy and Other Neuromodulation Therapies

William M. McDonald, M.D.
Thomas W. Meeks, M.D.
W. Vaughn McCall, M.D., M.S.
Charles F. Zorumski, M.D.

Electroconvulsive therapy (ECT) has proven to be one of the most effective somatic treatments for mood disorders (Kellner *et al.* 2012). ECT research has focused on techniques to maximize the efficacy of ECT and minimize side effects and to elucidate ECT's mechanism of action. In this chapter, the history of ECT is reviewed as well as the preclinical and clinical data on the mechanism of action of ECT and the relevant literature related to the efficacy and side-effect burden of ECT. Practical guidelines for the administration of ECT are outlined, including the efficacy of ECT in treating various psychiatric disorders, appropriate patient selection, stimulus settings and electrode placement, pretreatment medical evaluation, and management of the patient during acute, continuation, and maintenance courses of ECT. Finally, recent developments with investigative convulsive neuromodulation methods--individualized low-amplitude seizure therapy (iLAST), investigational magnetic seizure therapy (MST), and focal electrically administered seizure therapy (FEAST)--will be discussed.

History of Electroconvulsive Therapy

The development of ECT occurred at a time when few somatic treatments were available for psychiatric disorders and physicians were struggling to find treatments for severely ill psychotic patients. In 1935, Manfred Sakel induced hypoglycemic coma (i.e., insulin shock therapy) as a treatment for psychiatric patients, and in the same year Laszlo Meduna injected patients with pentylenetetrazol to induce convulsions in order to treat psychosis. Three years later, Italian psychiatrists Ugo Cerletti and Lucio Bini used electricity to induce seizures. Electroshock treatment proved safer and easier to administer than chemically induced seizures and replaced other methods of inducing seizures.

Modern psychopharmacology developed with the discovery of lithium (1949) and iproniazid (1957) for the treatment of mood disorders and the synthesis of the first antipsychotic, chlorpromazine (1952); the first tricyclic antidepressant, imipramine (1959); and the first benzodiazepine, chlordiazepoxide (1960). The development of psychotropic medications was associated with a decline in the use of ECT from the 1960s to the 1980s.

In the 1980s, the use of ECT began to increase in the United States (Thompson *et al.* 1994); however, the percentage of U.S. hospitals providing ECT declined by 43% from 1993 to 2009 (Case *et al.* 2013). ECT use in the United States is more common among older adults and white individuals (Luccarelli *et al.* 2020). Studies in Canada and Denmark demonstrated relatively stable rates of ECT utilization (Hundrup *et al.* 2017; Rapoport *et al.* 2006), whereas decreasing rates of ECT use have been reported in the United Kingdom and Australia (Plakiotis *et al.* 2012; Scott 2012). A metaanalysis of 18 international studies indicated declining global rates of ECT utilization from 1973 to 2013 (Lesage *et al.* 2016). By contrast, rates of ECT use have risen in China since 2014 and in the Netherlands from 2008 to 2015 (Ma *et al.* 2019; Verwey *et al.* 2017).

During this same period the results of the Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study (Rush *et al.* 2009) demonstrated the limited effectiveness of psychopharmacology for major depressive disorder (MDD) and supported the continued clinical relevance of ECT for patients who do not respond to medication management (Insel and Wang 2009; McCall 2007).

Since the 1980s, the safety of ECT has increased significantly with the introduction of sophisticated cardiopulmonary and electroencephalographic monitoring, better anesthetic agents, and the adoption of the brief-pulse stimulus machine. Today, ECT is arguably the fastest, most effective treatment for mood disorders. ECT is also one of the safest procedures performed under general anesthesia, with a mortality rate reported at 0.002% or less (Torring *et al.* 2017; Watts *et al.* 2011).

As with so many aspects of health care, the COVID-19 pandemic has created complications in ECT administration and associated declines in utilization rates globally. This probably relates to common recipients of ECT (older adults) being particularly at risk from COVID-19, the need for health care resources (including providers and personal protective equipment) to be shifted to care for those with COVID-19, and the increased viral transmission risk inherent in ECT (e.g., airway management, inability to socially distance) relative to other psychiatric care options (Lapid *et al.* 2020; Sienaert *et al.* 2020).

Mechanism of Action of Electroconvulsive Therapy

Despite the use of ECT in psychiatry for more than 80 years and extensive preclinical and clinical studies, the mechanisms underlying ECT remain poorly understood. The lack of mechanistic understanding is not unexpected given the multitude of changes induced by electrical stimulation and generalized seizures and the lack of understanding of the biology of major psychiatric illnesses. Here we focus on several hypotheses about the actions of ECT.

Anticonvulsant Hypothesis

Because a course of ECT has anticonvulsant effects, it is possible that its therapeutic benefits result from changes in neural excitability. This hypothesis is based on observations that a course of ECT results in increases in seizure threshold and decreases in seizure duration (Sackeim 1999), and the hypothesis focuses on changes in neurotransmitters and biochemical processes regulating neural excitability. GABA is the major inhibitory transmitter in the brain and a target for multiple anticonvulsant drugs, some of which are used to treat psychiatric disorders. Data from animal studies indicate increases in the threshold for bicuculline-and pentylenetetrazol-induced seizures following a series of electroconvulsive shock (ECS) treatments (Nutt *et al.* 1981; Plaznik *et al.* 1989). Because bicuculline and pentylenetetrazol inhibit $GABA_A$ receptors, these findings suggest that ECT alters GABAergic inhibition. Additionally, GABA levels increase in certain brain regions after ECS (Green *et al.* 1982), and evidence from magnetic resonance spectroscopy indicates that ECT increases GABA levels in the occipital cortex in humans (Sanacora *et al.* 2003). Changes in GABA levels suggest that there may be an increase in tonic inhibition after repeated seizures, and effects on GABA-mediated tonic inhibition are increasingly recognized as an important mechanism of several neuroactive drugs, including the novel neurosteroid antidepressant brexanolone (Farrant and Nusser 2005; Meltzer-Brody *et al.* 2018). In line with this research is the finding that increased frontal delta activity (i.e., postictal depression) may be a marker for ECT response (Azuma *et al.* 2007; Mayur 2006) and is associated with decreased cerebral blood flow in the immediate postictal period (Nobler *et al.* 1993).

Similarities to Antidepressant Medications

Numerous studies have examined whether there are common mechanisms between ECT and clinically used antidepressant medications. ECT, akin to antidepressants, normalizes changes in the hypothalamic-pituitary-adrenal axis associated with MDD (Yuuki *et al.* 2005). ECT also has significant effects on biogenic amines, including norepinephrine, serotonin, and dopamine, major targets for antidepressant medications. Certain antidepressants cause a_1-adrenergic receptor subsensitivity, and similar effects are observed with ECS (Nutt and Glue 1993). ECS has multiple other effects on the adrenergic system, including increased norepinephrine turnover and possibly decreased presynaptic a_2-adrenergic receptor sensitivity. ECS also alters the serotonin system, producing increased behavioral responses to serotonin agonists and altered 5-hydroxytryptamine type 2 (5-HT$_2$) receptor binding in the cerebral cortex (Fochtmann 1994; Nutt and Glue 1993; Sackeim 1994). Thus, 5-HT$_2$ receptor downregulation, like a-adrenergic receptor subsensitivity, may be a mechanism common to several antidepressant treatments.

Accumulating evidence suggests that depression and other psychiatric illnesses involve neuroinflammatory changes. While ECT is a stressor that can elevate inflammatory markers acutely, some evidence indicates that over a course of treatment, ECT causes the levels of certain cytokines, including tumor necrosis factor-a and interleukin-5 and -6, to be reduced, which may contribute to beneficial effects (Jiang *et al.* 2017; Yrondi *et al.* 2018).

Neuroplastic Effects of Electroconvulsive Therapy

An intriguing avenue for elucidating the effects of ECT is to determine how ECT alters the neurocircuitry of mood regulation and depression. This circuitry involves connections between and within regions of the prefrontal cortex, anterior cingulate gyrus, subgenual prefrontal cortex, anterior thalamus, and more traditional limbic structures (hippocampus and amygdala) (Drevets 2000; Seminowicz *et al.* 2004). Multiple studies have documented structural changes including cell loss (glia and possibly neurons) and diminished neuropil in several of these regions in subtypes of depression (Harrison 2002). Several studies have found that ECT increases regional brain volumes in specific areas, particularly in the hippocampus and amygdala (Gyger *et al.* 2021; Takamiya *et al.* 2018), but it is unclear whether these apparent neuroplastic effects contribute to treatment efficacy (Oltedal *et al.* 2018) or whether they are specific for depression (Thomann *et al.* 2017).

It also appears that different antidepressant treatments differentially affect metabolism in mood circuitry. Effective treatment with paroxetine increases metabolism in frontal regions while decreasing metabolism in the hippocampus, whereas cognitive-behavioral therapy results in the opposite effects (Goldapple *et al.* 2004; Seminowicz *et al.* 2004). In contrast, ECT diminishes metabolism in the prefrontal cortex and hippocampus (Nobler *et al.* 2001). Studies using functional connectivity neuroimaging indicate that ECT dampens hyperconnected neural circuits in the prefrontal cortex (Perrin *et al.* 2012) and alters network coherence in the default mode network, a brain circuit involved in self-referential thinking (Mulders *et al.* 2016); these latter effects correlate with treatment response. A major challenge in interpreting existing functional connectivity neuroimaging studies is that these studies have largely relied on analysis of group data rather than individual connectomes (Gratton *et al.* 2020). A recent study using individual connectome imaging methods indicates that ECT-induced impairments in verbal memory reflect widespread changes in connectivity between networks that include the default mode network, the frontoparietal control network, and the hippocampus, changes that were not observed in group data (Wang *et al.* 2020). However, the same type of individual-level analysis did not find correlates of mood improvement, suggesting that therapeutic effects may be heterogeneous across individuals. Results from this latter study are consistent with an emerging hypothesis that certain psychiatric treatments, probably including ECT, promote homeostatic synaptic plasticity (synaptic scaling) as a way of modulating neural circuits (Kavalali and Monteggia 2020).

Several antidepressant treatments, probably including ECT, have neurotrophic effects and result in neurogenesis in the dentate gyrus of adult rodents (Madsen *et al.* 2000; Malberg *et al.* 2000; Scott *et al.* 2000), an area that also shows increased volume in humans after ECT (Takamiya *et al.* 2019). These effects may involve changes in brain-derived neurotrophic factor and its receptor tyrosine kinase, as well as effects on the adenylate cyclase system, including the downstream effector cyclic adenosine monophosphate response element-binding protein (Conti *et al.* 2007; Duman and Vaidya 1998; Nestler *et al.* 2002; Schloss and Henn 2004). Recent evidence indicates that ECS increases survival and neuronal differentiation of newborn dentate cells (Ueno *et al.* 2019).

Other studies indicate that neurogenesis in the dentate gyrus of adult rodents results in survival of functional neurons that contribute to synaptic transmission (Song *et al.* 2002), suggesting that antidepressants, including ECT, may ultimately improve hippocampal function. Hippocampal changes are accompanied by increases in local angiogenesis and blood flow in specific subregions of the hippocampus (Hellsten *et al.* 2005; Newton *et al.* 2006), and other evidence indicates that ECS increases autophagy and membrane trafficking in the hippocampus, effects that could contribute to neurogenesis and reductions in cellular stress (Enomoto *et al.* 2016; Otabe *et al.* 2014). Although studies in rodents indicate that neurogenesis contributes to some behavioral effects of medications (Santarelli *et al.* 2003) and stress resilience (Anacker *et al.* 2018), it is unclear whether similar neurotrophic effects occur with ECT in humans. Studies using magnetic resonance spectroscopy to monitor regional changes in the glutamate-to-glutamine ratio, a marker of local intracellular excitatory transmitter metabolism (Hasler *et al.* 2007), indicate that depressed subjects have low glutamate-to-glutamine ratios that normalize with effective ECT (Michael *et al.* 2003; Pfleiderer *et al.* 2003).

Indications for and Efficacy of Electroconvulsive Therapy

Major Depressive Disorder

The summary statement by the American Psychiatric Association Task Force on Electroconvulsive Therapy (2001) supported the efficacy and safety of ECT. A metaanalysis of randomized controlled trials (RCTs) performed by the UK ECT Review Group (2003) confirmed the following about the efficacy of ECT for major depressive episodes (MDEs):

- ECT is more efficacious than sham ECT (shown in six RCTs; effect size, 0.91).
- ECT is more efficacious than antidepressant pharmacotherapy (18 RCTs; effect size, 0.80).

Given these data, ECT should no longer be considered a treatment of last resort (Beale and Kellner 2000; Kellner *et al.* 2005). Instead, ECT should be viewed as a potential first-line treatment when a rapid clinical response is essential in severely ill patients (e.g., those with active suicidal ideation, catatonia, or a compromised medical condition related to depression such as dehydration or malnutrition), when the patient has a history of a positive response to ECT, or when the patient (or surrogate decision maker) requests ECT over other treatment options. ECT's antidepressant effects are more rapid than pharmacotherapy, and clinical trials have confirmed a rapid resolution of suicidal ideation with ECT (Kellner *et al.* 2005; Lin *et al.* 2020; Patel *et al.* 2006). ECT was associated with lower overall mortality rates (including suicide deaths) among depressed patients compared with no ECT in a large Danish national patient database. ECT also reduces psychiatric readmission rates (Jorgensen *et al.* 2020; Slade *et al.* 2017).

Beale and Kellner (2000) argued that reserving ECT for patients with multiple failed medication trials for MDEs does not factor in the tolerability and efficacy of modern ECT and may lead to needless suffering on the part of the patient. Based on data modeled from the landmark STAR*D study of a stepped pharmacotherapy/psychotherapy algorithm for depression treatment, ECT was demonstrated to be cost-effective when used after only two trials of pharmacotherapy or psychotherapy had failed (Ross *et al.* 2018).

Patients with MDEs could have underlying unipolar or bipolar depression. A recent metaanalysis demonstrated equivalent remission rates with ECT for both unipolar and bipolar depression, although bipolar depression has a slightly faster response rate (Bahji *et al.* 2019). A retrospective study also indicated similar decreases in suicide rates among patients with unipolar or bipolar depression treated with ECT (hazard ratio ~ 0.80) in comparison to matched controls (Liang *et al.* 2018).

Patients who have undergone ECT rated it as a highly effective treatment (Parker *et al.* 2001) and developed significantly more positive views of ECT after experiencing the treatment than they had before treatment (Schmitgen *et al.* 2020). About 85% of patients who have undergone ECT would agree to a second course of ECT if needed (Bernstien *et al.* 1998). Similarly, about 85% of patients in a later study rated ECT as beneficial and well tolerated (Brown *et al.* 2018). ECT-related relief of depressive symptoms has also been associated with long-term improvements in health-related quality of life (Giacobbe *et al.* 2018).

Predictors of Response

Consistent positive predictors of response and remission among patients with MDEs treated with ECT include older age and the presence of psychotic symptoms (Dombrovski *et al.* 2005; Haq *et al.* 2015; van Diermen *et al.* 2018). Other positive predictors of remission or response cited in several studies include greater psychomotor retardation, shorter duration of depressive episode, and greater depression severity (Haq *et al.* 2015; Heijnen *et al.* 2019; van Diermen *et al.* 2018). One analysis attributed the association between older age and ECT response to the higher rate of psychosis and psychomotor changes among depressed older adults rather than to age itself (van Diermen *et al.* 2020). Several recent studies have also reported that early symptomatic response (in weeks 1-2) to ECT is predictive of ultimate remission (Birkenhager *et al.* 2019; Lin *et al.* 2019; Martinez-Amoros *et al.* 2018). Patients with comorbid personality disorders and a history of medication treatment resistance may be less likely to respond to ECT (Feske *et al.* 2004; Haq *et al.* 2015; Heijnen *et al.* 2010; Nordenskjold *et al.* 2012; Rasmussen 2015; Yip *et al.* 2021).

A recent review of baseline neuroimaging predictors of ECT response in MDD indicated some evidence for the following positive predictors: lower hippocampal and anterior cingulate volume, higher amygdala volume, and connectivity between prefrontal and default mode networks. Negative predictors included deep white matter hyperintensities and medial temporal atrophy (Levy *et al.* 2019; Schmitgen *et al.* 2020). Several investigations have examined possible genetic determinants of ECT response in depression, with the most common candidates being genes regulating dopamine and serotonin function and growth factors such as brain-derived neurotrophic factor and vascular endothelial growth factor. Results have been largely inconsistent except for the catechol-O-methyltransferase gene. Homozygotes for the Val allele have increased catechol-O-methyltransferase activity, causing accelerated dopamine breakdown and a relative hypodopaminergic state that appears to increase the likelihood of responding to ECT (Benson-Martin *et al.* 2016). Efforts to correlate seizure characteristics with clinical outcome have been largely disappointing, the most consistent (albeit small) association being postictal depression predicting better response (Francis-Taylor *et al.* 2020).

Mania

Case studies and at least seven randomized clinical trials suggest that ECT is beneficial in the treatment of mania associated with bipolar disorder, demonstrating rapid effects and notable response rates (Elias *et al.* 2021; Fink 2001, 2006). Retrospective analysis of over 14,000 inpatients admitted from 2012 to 2014 for bipolar manic episodes in over 4,400 U.S. hospitals revealed that ~ 18% underwent ECT (Patel *et al.* 2019). In a prospective, controlled trial, Small *et al.* (1988) compared the efficacy of ECT with that of lithium in the treatment of mania. Patients who underwent ECT improved more during the first 8 weeks of treatment than did patients who received lithium. Nevertheless, after 8 weeks of treatment, ECT and lithium were comparable in efficacy. Other reports have suggested ECT may be more effective for acute mania than lithium and at least as effective as antipsychotics. ECT has proved helpful in cases of mania that were resistant to standard pharmacotherapies (Elias *et al.* 2021). The most notable limitation in prospective trials of ECT for mania is the small sample sizes; recruitment of this population is complicated by lack of patient insight into their diagnosis and higher standards for obtaining informed consent for ECT compared with pharmacotherapy.
